hallmark feature: uveitis and glaucoma (see Chapters 263 and 264). Digital tonometry, in which the IOP is crudely assessed by compressing the globe against the orbital rim, is completely unreliable. The Schiøtz tonometer is reliable but awkward to use and requires conversion tables to convert the scale reading to the standard unit of IOP (millimeters of mercury). The availability of easily used and reasonably priced applanation tonometers such as the Tonopen has made measurement of IOP easier in all species, particularly cats. Unlike the Schiøtz tonometer, the Tonopen measures IOP directly and does not require any conversion. It can also be held horizontally and therefore allows measurements to be performed with the patient's head held in a normal, relaxed position. Finally, it has a small probe that permits easy measurement of IOP in even the smallest feline and pediatric canine eyes.

The Tonopen comes with an excellent instructional video and manual; however, the following tips may help the veterinarian achieve optimal results. A drop of topical anesthetic is applied to the cornea. A disposable cover is placed over the Tonopen tip; and the pen is turned on with firm, somewhat protracted pressure on the large black button about one third down the shaft. The equipment should be periodically calibrated according to the manufacturer's directions. Correct patient restraint is essential. The patient should be lightly restrained so as to not artificially raise IOP. In particular, direct pressure on the jugular veins by the holder or by a collar should be avoided. Similarly, no pressure should be exerted on the globe itself via the eyelids. This is best achieved by having an assistant (not the owner) restrain the patient's head, holding the angle of the mandible and the occiput. The Tonopen is then held in the dominant hand, and the patient's eyelids are gently parted using the nondominant hand so that pressure is applied to the underlying orbital rim, not the globe. The hand holding the Tonopen should then be rested onto the hand holding the eyelids or onto the patient's head itself. Very small, rapid (almost tremorlike) movements of the Tonopen away from and back toward the cornea such that the cornea is very lightly "blotted" with the Tonopen tip will enhance the reliability and reproducibility of the readings while reducing the number of readings necessary. Particular attention should be paid to the "approach angle" of the Tonopen tip to the cornea. The flat surface of the tip should be exactly parallel to the corneal surface. This is best achieved by viewing the interface between the cornea and the tip from the side. Said another way, the Tonopen itself should approach the globe as close to perpendicular to the corneal surface as possible. Therefore, because of corneal curvature, the approach angle must be changed dramatically if any area other than the central cornea is used or if the patient's globe moves.

Each time the cornea is appropriately "blotted" with the probe, an electronic tone will advise the operator that a reading has been obtained. When a suitable number of readings have been obtained, a tone of a different pitch will sound, and no further readings can be obtained without restarting the Tonopen using the large black button again. The number of readings required to achieve an average varies, depending on how disparate the readings are from each other and from the normal physiologic range.

A small digital screen displays the IOP in mm Hg and provides an estimate of the "reliability" (coefficient of variance) of the result. This appears as a small bar above one of four percentage readings. This bar should be above the 5% mark, or tonometry should be repeated for that eye. Across large populations, normal canine and feline IOP is reported as approximately 10 to 20 mm Hg. However, variation is noted between individuals, technique, and time of day. Therefore comparison of IOP between right and left eyes is critical to interpretation of results. A good rule of thumb is that IOP should not vary between eyes of the same patient by more than 20%.

Aqueous flare is a pathognomonic sign of uveitis and is the result of breakdown of the blood-ocular barrier, with subsequent leakage of plasma proteins into the anterior chamber where, with special technique, they can be seen. Aqueous flare is best detected using a very focal, intense light source in a totally darkened room. The passage taken by the beam of light is viewed from an angle. In the normal eye a focal reflection is seen where the light strikes the cornea. The beam is then invisible as it traverses the almost protein- and cell-free aqueous humor in the anterior chamber. Because of presence of lens proteins, the light beam becomes visible again as a focal reflection on the anterior lens capsule and then as a diffuse beam through the body of the normal lens. If uveitis has allowed leakage of serum proteins into the anterior chamber, these proteins will cause a scattering of the light as it passes through the aqueous (Fig. 248-3). This is called *aqueous flare* and is seen as a beam of light traversing the anterior chamber and joining the focal reflections on the corneal surface and the anterior lens capsule or iris. A slit lamp provides ideal conditions for detecting aqueous flare; however, the beam produced by the smallest circular aperture on the direct ophthalmoscope, at brightest illumination, in a completely darkened room, held as closely as possible to the cornea, and viewed transversely will also provide excellent results. The slit beam on the direct ophthalmoscope is not as intense as the small circular aperture and does not provide as many "edges" of light against which flare can be appreciated most easily. Aqueous flare is best

Fig. 248-3 Aqueous flare is present in this dog with anterior uveitis. A very focal, intense beam of light is directed across the anterior chamber and viewed transversely with magnification in a totally darkened room. Leakage of serum proteins into the anterior chamber causes scattering of the light as it passes through the aqueous between the cornea and iris.

seen against a black “backdrop,” which in the eye is the pupil. Therefore assessment of flare is sometimes easier after complete pupil dilation. Combined assessment of IOP and aqueous flare should be performed whenever glaucoma or uveitis is suspected because of the frequency with which these conditions coexist.

Fundic examination is probably the greatest challenge in the ophthalmic examination. Fortunately anterior segment abnormalities tend to outnumber fundic abnormalities in general practice. However, funduscopy is critical in the assessment of animals presenting with visual disturbance, pupil abnormalities, or systemic disease. Traditionally there have been two methods for viewing the fundus: indirect and direct ophthalmoscopy. Recently Welch-Allyn and Keeler have both introduced new ophthalmoscopes (the Panoptic and the Wide-Angle Twin Mag, respectively) that combine some of the best features of both methods. Regardless of which method is used, funduscopy requires full pupil dilation. This is best achieved by examining the patient at least 15 minutes after topical application of a single drop of tropicamide.

THE DIRECT OPHTHALMOSCOPE

This instrument hangs on the walls of most veterinary examination rooms the world over and yet is not the best method for examining the fundus. It is used by turning the lens power to “0”, selecting the largest circle of light that it emits, turning the light to almost full brightness, turning the room lights off or to a dim setting, and resting the brow rest of the ophthalmoscope against the operator’s brow. Ideally the operator’s right eye should be used for examining the patient’s right eye and vice versa; although some people have trouble using their nondominant eye. The examiner should hold the animal’s eyes open while an assistant holds the head steady and begin viewing at arm’s length from the patient and move around until a bright tapetal reflection is obtained (as for retroillumination). The examiner should then slowly approach the animal, while always aiming at the tapetal reflection of the eye to be examined. Good focus in a normal patient should be reached within just a few centimeters of the eye. Therefore it is sometimes useful to extend the index finger of the hand holding the ophthalmoscope and rest the finger against the patient’s cheek.

The direct ophthalmoscope presents a highly magnified, upright image of a very small region of the patient’s fundus. In compliant human patients this instrument can then be used to slowly and sequentially examine the whole fundus in minute detail. However, in veterinary patients this small field of view frequently means that areas of the fundus, particularly peripherally, are never examined and that one area of the retina cannot be compared readily to another region.

THE INDIRECT OPHTHALMOSCOPE

Because of the large field of view achieved with indirect ophthalmoscopy, this is the preferred method for examining the dog or cat fundus. This larger field of view permits the examiner to compare regions of the fundus against each other so that focal areas of subtle pathology may be

detected by comparison with neighboring normal areas. It also makes a complete examination of the whole fundus more likely and easier than when performed with direct ophthalmoscopy. The perceived downfalls are that the image is less magnified; however, this can be countered by moving closer to the patient while performing indirect ophthalmoscopy or by a subsequent (more magnified) examination of any “suspect” areas using the direct ophthalmoscope. Another difficulty for beginning ophthalmoscopists is that indirect ophthalmoscopy produces an inverted view. This makes navigation around the fundus and correct anatomic localization of lesions a little more difficult at first, but this disadvantage can be readily overcome with practice. A Volk 20D or 2.2 Pan Retinal indirect lens is ideal for examining the small animal fundus.

MONOCULAR INDIRECT OPHTHALMOSCOPES

Monocular indirect ophthalmoscopes have been introduced that fit to common existing battery handsets in practice, are reasonably easily mastered, and produce a view of the fundus with many of the best features of those produced using direct and indirect ophthalmoscopy. The image is upright and moderately magnified and includes more of the fundus than is possible with the direct ophthalmoscope but less than that provided by the indirect ophthalmoscope.

OTHER DIAGNOSTIC TECHNIQUES IN VETERINARY OPHTHALMOLOGY

Unlike assessment of other less accessible organs, visual examination of the eyes frequently provides all of the clues necessary to reach a clinical diagnosis. However, ancillary tests can provide valuable information in specific disease conditions.

The Schirmer tear test (STT) records basal and reflex tearing as number of millimeters of wetting of a strip of absorbent paper placed in the lateral aspect of the ventral conjunctival fornix for 1 minute. The lateral aspect is used to ensure that the strip lightly abrades the cornea and produces reflex tearing. If the strip is placed more medially, it may be prevented from touching the cornea by the third eyelid. The STT should be performed before application of any topical solutions, particularly anesthetic drops. General anesthesia and sedation also cause a temporary depression of normal tearing (for at least 48 hours). Normal STT values for dogs are well established; an STT reading of more than 15 mm in 60 seconds is considered normal. Wetting of less than 10 mm in 60 seconds is abnormal and is usually associated with evidence of keratoconjunctivitis. Wetting of 10 to 15 mm in 60 seconds represents a “gray zone” and warrants careful assessment and sometimes reassessment in light of clinical signs. The range of reported STT values in normal cats (3 to 32 mm; mean = 17 mm in 60 seconds) is much wider and more difficult to interpret than in dogs. However, experience suggests that lower readings than the reported mean can frequently be expected in completely normal cats. This is probably because of autonomic control of tear secretion and short-term alterations in tear flow as a result of stress in the examination room.

Feline STT values should still be recorded and interpreted in conjunction with clinical signs.

Application of fluorescein dye to the cornea can yield a large amount of information. A few drops of irrigation solution are trickled over a strip impregnated with fluorescein to liberate dye onto the cornea. Care should be taken not to touch the strip onto the cornea. Excess dye is then rinsed from the corneal surface, and the eye examined with either white or cobalt blue light. This simple, water-soluble dye has great affinity for the hydrophilic corneal stroma but is not absorbed by epithelial cells or Descemet's membrane. Therefore its most common use is identification and characterization of corneal ulcers. Excitement of the fluorescent dye with a cobalt blue light can assist with identification of minor lesions; however, excessive dye must be adequately rinsed from the cornea to avoid overinterpretation of normal pooling. Small, "scuffed" areas of corneal epithelium are occasionally seen following the STT.

Passage of dye down the nasolacrimal duct is referred to as the *Jones test* and is used to assess functional and anatomic patency of the nasolacrimal apparatus. *Seidel's test* also uses fluorescein stain. This test is used to assess integrity of the cornea following suspected penetrating trauma or ulceration and to guide decisions regarding management of such wounds. In Seidel's test the excessive dye is not rinsed from the cornea and the surface is examined with a cobalt blue light and magnification for possible perforation. Leakage of aqueous humor will cause small rivulets to form in the fluorescein dye pooled on the corneal surface.

Rose bengal stain is retained by devitalized corneal or conjunctival epithelial cells. Recent studies have suggested that even changes in amount or quality of some normal tear film components such as mucin and albumin can cause otherwise viable epithelial cells to retain rose bengal stain. Therefore its clinical utility is detection of subtle epithelial abnormalities as seen in keratoconjunctivitis sicca ("dry eye") or the dendritic ulcers that are pathognomonic for canine and feline herpesvirus keratitis. Rose bengal and fluorescein stains may affect culture and virologic results and should be applied following collection of microbiologic samples. Rose bengal is also epitheliotoxic and may cause discomfort in some animals; therefore it should be reserved for cases in which it may provide useful additional information.

Retropulsion of the globe is a simple but useful method for investigating orbital disease. It is performed by applying gentle digital pressure to both globes in a posterior direction through closed lids. The resistance to retropulsion and the resilience with which the globes "spring" back against the retropulsive force are subjectively assessed. Retropulsion of the globe in a variety of directions may further localize orbital masses or outline smaller masses that would be missed by direct caudal retropulsion only.

Cannulation of the nasolacrimal puncta and gentle flushing with saline can be readily performed in most conscious dogs following application of a topical ophthalmic anesthetic. However, it is particularly challenging in cats without sedation or general anesthesia. A 3/4-inch, 22- or 24-gauge Teflon intravenous catheter without the stylette is easy to use and usually well tolerated; however, more

rigid, specialized metal cannulae are also available. The inferior or superior punctum is identified and cannulated. Gentle injection of saline through one punctum should elicit flow from the other in the same eye without any resistance. Following assessment of patency between the superior and inferior puncta, gentle digital obstruction of the noncannulated punctum should cause passage of the solution through the nasolacrimal duct and out the ipsilateral nostril. Frequently in cats and brachycephalic dogs, the nasolacrimal ducts open caudally enough in the nose that flush solutions are not evident at the external nares but exit into the nasopharynx and then the oral cavity. Inclusion of a small amount of fluorescein in the flush solution and observation of the nares and oral cavity with a cobalt blue light source may assist with identification of patency. Fluorescein should be avoided if culture or cytology of nasolacrimal fluid is intended.

Cytology, aspirates, and biopsies can be harvested relatively easily from ocular tissues, sometimes without sedation. Scraping or aspirate samples from the eyelid are collected using the same procedures as elsewhere on skin; however, particular care is taken not to damage the eyelid margin and to direct the instruments used away from the globe. Scrapings from the cornea or conjunctiva are performed following several applications of topical anesthesia and using either a Kimura platinum spatula or the dull, handle-end of a scalpel blade. Cytology specimens are spread gently onto glass slides and stained with Diff Quik and/or Gram stains. Conjunctival "snip biopsies" can usually be harvested following application of topical anesthetic and without sedation. A small section of conjunctiva is gently "tent up" with fine forceps and resected with small tenotomy scissors (see Fig. 260-3). Minimal and careful handling is essential to avoid artifactual disruption of this delicate tissue before histologic interpretation. Corneal biopsies are usually gathered by lamellar keratectomy and require general anesthesia, magnification, and sometimes neuromuscular blockade and therefore are more commonly collected by those with specialty training.

Imaging techniques for the globe and orbit are becoming more widely available. These are particularly useful when opacity of the ocular media (cornea, lens, aqueous humor, or vitreous) prohibits detailed examination of intraocular structures and for diagnosis of orbital disease. Ultrasonographic assessment has proved particularly useful. A 7.5- to 10-MHz (or preferably 12 to 20 MHz) probe is required. Examination of a conscious patient following application of topical anesthetic is preferred since sedation tends to cause ventral rolling of the eyeball and enophthalmos, which make obtaining adequate images difficult. Transcorneal or transpalpebral approaches are used most commonly; however, a temporal approach has been described for retrobulbar examination. Sterile coupling gel is applied to the cornea or lids, and the probe is applied with gentle pressure sufficient to ensure a clear image. Particular care should be taken if corneal perforation is imminent.

Radiographic assessment is particularly useful for diagnosis of orbital fractures, assessment of bony involvement when invasive tumors are suspected, or identification of radiopaque foreign bodies, particularly gunshot injuries.

Magnetic resonance imaging and computed tomography scanning provide valuable information regarding extent and character of orbital disease and also provide surprisingly good intraocular definition.

Gonioscopy is examination of the iridocorneal angle (ICA). In dogs a small plastic corneal lens is required. In cats (because of their large corneas and degree of corneal curvature), magnification and a focal light source (i.e., an otoscope head) will provide some assessment of this area. However, this should still be supplemented with a gonioscopic lens before a final assessment is made. The clinician should focus initially on the iris and then follow it out peripherally until the ICA and pectinate ligaments come into view. These are usually long and relatively straight (especially in cats) and should have large spaces between them. They are usually pigmented to the same degree as the iris. Examination of the ICA provides essential information for diagnosis and prognosis of glaucoma and uveitis. Although this technique

is learned relatively easily, familiarity with angle anatomy and interpretation of abnormal findings require practice.

Anterior chamber, vitreous, and subretinal aspirates are sometimes used in the assessment of uveitis or intraocular masses if less invasive techniques have not yielded a diagnosis. Samples gathered in this fashion can be examined serologically or cytologically or submitted for PCR culture and sensitivity testing. Due to the risk of irreversible globe damage during these procedures, they are best performed by ophthalmologists.

The electroretinogram is a measure of retinal electrical activity in response to stimulation with light. It is a routine part of assessment of patients before cataract surgery and may also be used to differentiate blindness resulting from retinal and optic nerve or central neurologic disease. The specialized equipment needed and knowledge of the technique limit this study to specialist ophthalmology practices.

CHAPTER 249

Ocular Pharmacology

DANIEL A. WARD, Knoxville, Tennessee

Ocular disease represents a considerable segment of most small animal veterinary practices. The majority of ocular disease in small animals is addressed by pharmacologic management, either alone or in conjunction with surgery. Therefore it is beneficial to most small animal veterinarians to have an understanding of ocular pharmacology. The goal of this chapter is to provide such a foundation.

When making decisions regarding medical management of ocular disease, one must first consider which tissue within the eye is the target of therapy. It is a mistake to consider the eye as a homogenous tissue. Rather, the eye should be considered a heterogeneous structure containing a number of substructures as potential therapeutic targets, including the lids, conjunctiva, corneal epithelium, corneal stroma, anterior uvea (consisting of the iris and ciliary body), iridocorneal angle, lens, vitreous, choroid, retina, sclera, and orbital tissue (which includes fat, muscle tissue, nervous tissue, vasculature, and bone). The reason for this separation is that there are a number of ways of delivering medication to the eye and different ocular targets are best reached by different routes.

OCULAR SURFACE

Topical application of medication is generally the preferred route of administration for ocular surface disease, which includes disorders of the conjunctiva and corneal epithelium (e.g., conjunctivitis and superficial keratitis). Because topical agents can be applied directly to the ocular surface, very high drug concentrations can be achieved in these tissues.

At the same time, several precorneal factors exact constraints on achieving high concentrations at the ocular surface following topical delivery. For example, the volume of a typical eyedrop is approximately 50 μ l. But the tear film of a normal canine eye can contain approximately only 10 μ l, meaning that 80% of the applied drop is immediately lost through nasolacrimal drainage or spillage onto the face. In addition, a topically applied drop is immediately diluted by the tears present on the ocular surface at the moment of application. When the eye is painful (as is usually the case with ocular disorders), lacrimation in response to the pain can be substantial, making the dilutional effect even greater. Further dilution occurs as a result of reflex lacrimation that occurs when the

eyedrop makes contact with the ocular surface. Nasolacrimal drainage offers a constant and substantial sump for draining drug away from the ocular surface, and it is increased when the eye is painful because of an increased blink rate (in humans, each blink forces 2 μ l of tears into the nasolacrimal duct). Taken together, these volume limitations, dilution, and tear drainage dictate that only about 1% to 7% of any eyedrop applied to the eye is actually available to ocular tissues and that peak effects are relatively fixed at 20 to 60 minutes following application. The extent of these losses will vary somewhat based on the physicochemical properties of the drug under consideration, but ocular pharmacokinetic research has shown that these parameters hold true for almost all topically applied drops.

There are several strategies for maximizing bioavailability to the ocular surface. Increasing viscosity by using viscous solutions or ointments as drug vehicles extends contact time and reduces the effects of dilution and nasolacrimal drainage. For example, addition of viscous polymers such as polyvinylpyrrolidone or hydroxypropyl methylcellulose to eyedrops may increase bioavailability by 50% to 100%, primarily by reducing the dilutional effect. Simple ointments (drug dissolved or suspended in long-chain hydrocarbon oil) and compound ointments (drug incorporated in biphasic dispersion of water-in-oil or oil-in-water) also increase availability to the ocular surface. These agents probably create a drug reservoir that retards nasolacrimal drainage, which in turn tends to enhance both the maximal attainable tear film concentration and the duration of therapeutic effect. However, it should be noted that these parameters are highly dependent on the physicochemical composition of the drug in question. For example, in rabbit studies of ointment and solution formulations of the hydrophilic antiglaucoma agent pilocarpine and lipophilic corticosteroid fluorometholone, the ointment form of both agents increased the maximal attainable concentration twofold to threefold compared to the solution form. However, duration of action was significantly prolonged (by approximately threefold) only with the ointment formulation of fluorometholone.

Occlusion of the nasolacrimal puncta following eyedrop administration is sometimes advocated in humans as a means of increasing concentrations and prolonging duration of action. However, tear film concentration of most eyedrops falls by only about 10% per minute; thus punctal occlusion would have to be maintained for several minutes to have an appreciable effect on duration. A simpler alternative may be to repeat instillation once or twice at 5- to 10-minute intervals. We have observed the benefit of this strategy with the antiglaucoma eyedrop apraclonidine, in which administration of a single drop has virtually no effect on intraocular pressure in dogs, yet application of 2 drops 5 minutes apart reduces intraocular pressure by 30%.

In the foregoing discussion of topical drug application for ocular surface disease, it is implied that drops or ointments are applied at regular intervals—so-called “*pulsed delivery*.” Despite the strategies mentioned previously to improve drug concentration in the tear film, pulsed therapy will always be associated with concentration peaks

and nadirs, with nadirs generally falling into the subtherapeutic range for at least a portion of each interdosing interval. Variation in concentration can be reduced by nonpulsed delivery techniques. Although not commonly used in small animal practice, such techniques include constant rate pump systems that can be attached to subpalpebral lavage systems, biodegradable drug delivery devices, and application of hydrophilic soft contact lenses soaked in medication.

Apart from enhanced drug concentration, topical delivery to treat ocular surface disorders is desirable because systemic side effects are reduced compared to systemic administration. There are certainly exceptions to this general rule. For example, topical β -blockers used in the treatment of glaucoma can cause bradycardia and bronchospasm, especially in smaller patients. Topically applied corticosteroids given at concentrations and frequencies often used clinically commonly induce polydipsia or polyuria, suppression of the pituitary-adrenal axis, and hepatic vacuolar changes. But in general, untoward systemic side effects are less frequent with topical than with systemic administration.

Corneal surface disease is sometimes treated with subconjunctival injection. In this technique a small depot of drug (usually either a corticosteroid or antibiotic) is injected beneath the bulbar conjunctiva 4 to 6 mm posterior to the limbus. The disposition of an agent delivered in this way varies; some regurgitates through the conjunctival puncture to bathe the cornea (at which point it essentially behaves as a continuously applied topical drop), some enters the systemic circulation, and some diffuses directly into and possibly through the sclera. For treatment of ocular surface disorders, the regurgitated fraction is probably the most important. In general, drugs given by this route have a longer duration of action than topically applied drops. Repository corticosteroids (e.g., methylprednisolone acetate and triamcinolone acetonide) may provide 3 to 4 weeks of antiinflammatory activity following a single injection. The principle drawback to subconjunctival injection is that, should a complication arise necessitating discontinuation of the agent (e.g., a dog with chronic superficial keratoconjunctivitis or “*pannus*” that develops a corneal ulcer), it may be difficult or impossible to remove. Recommended subconjunctival drug doses are listed in Table 249-1.

CORNEAL STROMA AND ANTERIOR UVEA

Delivery of drug to the corneal stroma and anterior uveal tissues by topical application is hindered by the same precorneal factors addressed previously. However, treatment of these tissues is further hindered by the corneal epithelial barrier, which severely limits passage of all but the most lipophilic compounds. For example, most topical antibiotics are hydrophilic and reach low concentrations in the corneal stroma. Therefore treatment of bacterial stromal abscesses in which the stroma is infected but the overlying epithelium is intact may be difficult because most commonly available topical agents will not reach the site of infection in appreciable concentrations. To overcome this problem, the clinician can periodically denude the epithelium overlying the abscess, or alternatively

Table 249-1

Subconjunctival Drug Dosages

Drug	Dosage (milligrams)*
Antibiotics	
Amikacin	25
Cefazolin	100
Gentamycin	20
Kanamycin	20
Oxacillin	50
Tobramycin	20
Vancomycin	25
Corticosteroids	
Betamethasone	1
Dexamethasone	1
Methylprednisolone	5
Triamcinolone	5
Mydriatics	
Atropine	1

*Administered volume should not exceed 0.5 ml in dogs or cats and should not exceed systemic dose in exotic animals.

coapply the epitheliotoxic topical anesthetic proparacaine at the same time the antibiotic is applied. Another approach is the use of topical formulations of chloramphenicol. As an amphipathic agent, it can take on either polar or nonpolar characteristics, depending on its local microenvironment. It is thus capable of superior corneal epithelial penetration, and we have successfully treated a number of refractory bacterial stromal abscesses by simply switching antibiotic therapy from a more hydrophilic agent (such as an aminoglycoside) to chloramphenicol. However, it bears emphasis that this approach is only useful if the offending organism is sensitive to chloramphenicol. Also, it is important to recall that chloramphenicol is a bacteriostatic antibiotic and bactericidal agents are preferred for corneal infections when practicable.

Topical corticosteroids are often used in the treatment of inflammation of the deep corneal stroma and anterior uvea. Tremendous differences exist among topical corticosteroids with respect to both potency and corneal epithelial penetrability. For example, it is generally accepted that dexamethasone is a more potent steroid base than prednisolone. But most dexamethasone products are formulated as sodium phosphate salts, which are highly polar and penetrate corneal epithelium poorly. Therefore these products are very effective for treatment of ocular surface inflammation but less so for anterior uveitis. By contrast, the acetate salt of prednisolone is very lipophilic and penetrates the corneal epithelium quite well. Therefore it is generally more effective than dexamethasone sodium phosphate for treatment of anterior uveitis.

For some agents it is possible to enhance drug delivery through the corneal epithelium by formulating a prodrug with superior lipid solubility that is then metabolized by corneal stromal enzymes once the epithelial barrier has been breached. Examples of such drugs include the mydriatic phenylephrine oxazolidine (which is metabolized to

phenylephrine) and the antiglaucoma agents dipivefrin (metabolized to epinephrine) and latanoprost (metabolized to prostaglandin F_{2a}).

Even assuming adequate corneal epithelial penetration, deep corneal stromal and anterior uveal drug concentration following topical delivery may be further complicated by enzymatic degradation, dilution and washout by aqueous humor, protein binding, and (for uveal delivery) binding to melanin.

Although a number of enzyme systems such as catechol O-methyltransferase, monoamine oxidase, and glucuronide transferase are present within corneal stroma, it is generally not considered a major site of topical drug degradation. Rather, these enzyme systems are exploited in the pharmaceutical formulation of agents to enhance corneal epithelial penetration (as are the lipophilic prodrugs mentioned previously) or to reduce systemic absorption or duration of action. Agents using the latter mechanism are termed "soft drugs." Examples include an analog of atropine, which retains the mydriatic potency of atropine but has a much shorter duration of effect on the diseased eye and no effect on the fellow eye, and "soft" steroids such as loteprednol etabonate, which retain ocular antiinflammatory activity but have fewer ocular and systemic side effects.

Dilution and washout of topically applied drugs destined for the anterior uveal tissues is predictable but unavoidable. The drugs most commonly used to target these tissues are steroidal and nonsteroidal antiinflammatory agents, antiglaucoma medications, and drugs that alter pupil size. The precorneal effects and corneal epithelial barrier mechanisms discussed previously, as well as dilution and washout within aqueous humor, do limit uveal concentrations attainable with these agents. Despite this, topical delivery is still generally preferred because systemic delivery of these drugs must surmount the even more formidable blood-aqueous humor barrier. In the normal dog eye aqueous humor is replenished at the rate of approximately 1% per minute, meaning that the entire aqueous humor volume is replenished approximately once every 100 minutes. Yet most compounds active within the anterior uvea retain activity for far longer (i.e., there is a pharmacokinetic-pharmacodynamic dissociation). This phenomenon can variously be explained by pharmaceutical formulations that prolong the residence time of the drug on the ocular surface, the presence of bioactive metabolites, binding to, and subsequent metered release from, ocular proteins and melanin, and activity through second messenger systems.

Protein and melanin binding can be beneficial or detrimental to the anterior uveal activity of a drug following topical application. For example, most nonsteroidal antiinflammatory drugs are highly protein bound (e.g., >99% for flurbiprofen), yet only free drug has antiinflammatory efficacy; thus relatively high anterior segment concentrations must be achieved to retain antiinflammatory efficacy. Similarly, many mydriatic agents and antiglaucoma β -blockers are avidly bound by melanin. Once saturated, they may be released slowly and provide a sustained duration of activity.

As with treatment of ocular surface diseases, disorders of the corneal stroma and anterior uveal tissues are sometimes treated by subconjunctival injection. The route by

which these drugs ultimately enter these tissues (transcorneal, transscleral, or from the systemic circulation) varies greatly, depending on the drug in question. In general, higher concentrations are achieved with subconjunctival injection than with topical application.

LENS

The lens is almost never a target of drug delivery, although this may change with development of aldose reductase inhibitors to treat diabetic cataracts. Presently the primary concern regarding drug delivery to the lens is unintended drug accumulation within the lens and subsequent cataract formation. For most drugs studied, accumulation in the lens fortunately does not occur, probably because of anatomic features of the lens itself. The presence of an anterior layer of epithelium and densely packed lens fibers subjacent to the epithelium make the lens a very nonporous structure that likely resists movement of hydrophilic compounds.

VITREOUS

The primary indication for drug delivery to the vitreous is infectious endophthalmitis. Topical delivery of antibiotics to the vitreous body is ineffective because not only must the antibiotics survive passage through and dilution within the tear film, cornea, and aqueous humor in adequate concentrations and avoid uveal melanin binding, they must also traverse the relatively closed lens-iris diaphragm. Higher vitreal concentrations are achieved with systemic delivery or intravitreal injection.

Systemically administered drugs enter the vitreous by way of the ciliary, retinal, or choroidal circulation, although passage via these routes is limited by the blood-aqueous humor and blood-retinal barriers. In addition, once a drug has reached the peripheral vitreous by one of these routes, further migration throughout the vitreous is slow and inconsistent, regardless of the physicochemical properties of the drug, and significant accumulation often does not occur. The only reliable way of achieving homogenous drug distribution within the vitreous is via intravitreal injection. The technique is straight forward with adequate training and assuming important

safeguards are taken. The patient is anesthetized with a short-acting general anesthetic, the ocular surface is sterilized with dilute (1:10) povidone-iodine (Betadine) solution, the limbus is grasped with a small-toothed forceps, and a 22-gauge needle with syringe attached is inserted into the globe 8mm posterior to the limbus. To avoid inadvertent rupture of the posterior lens capsule and globe-threatening uveitis, the needle must be directed toward the center of the vitreous body, *not* the center of the globe itself. Careful attention must be paid to the volume and amount of agent injected because many drugs (especially antimicrobial agents) have a dose-dependent propensity for retinal toxicity. Recommended intravitreal dosages are listed in Table 249-2.

CHOROID AND RETINA

Many disorders of the canine posterior segment are developmental or degenerative and are not as yet amenable to medical therapy. The most commonly encountered conditions that are effectively managed medically are bacterial and fungal infections and some vascular disorders. Because they tend to affect both the choroid and the retina, these structures are considered together.

As with the vitreous, topical delivery of drugs invariably fails to reach therapeutic concentrations in the retina. Better concentrations are generally achieved with systemic administration and in some instances posterior subconjunctival administration. Following systemic administration in normal dogs, high drug concentrations are generally achievable in choroidal tissue because of the permeability of the choroidal vasculature. However, movement of drugs from choroidal tissue into the retina is hindered by the “outer” blood-retinal barrier composed of tight junctions between adjacent retinal pigment epithelial cells. Similarly, systemically administered agents are restricted from entering retinal tissue from the retinal vasculature because of tight junctions between adjacent retinal vascular endothelial cells (the “inner blood-retinal barrier”). However, in most circumstances in which drugs need to be delivered to retinal tissue (e.g., an antifungal agent in a patient with chorioretinal blastomycosis), these barriers are dysfunctional secondary to inflammation, and drug entry is facilitated.

Retrobulbar injection has been used successfully in the treatment of chorioretinal disease in experimental animals and is occasionally advocated for clinical use in humans, but this route is not commonly used in the treatment of chorioretinal disease in domestic animals.

EYELIDS AND ORBIT

In general, eyelid and orbital diseases can be viewed as integumentary and deep soft-tissue disorders, respectively. As such, they are usually treated with systemically administered drugs. Management of disorders of the eyelid margin (such as meibomian gland infection) may be supplemented by direct application of ophthalmic ointments. In rare instances orbital diseases are treated by retrobulbar injection.

Table 249-2
Intravitreal Antibiotic Dosages

Antibiotic	Dosage (micrograms)*
Amikacin	400
Cefazolin	2250
Gentamycin	100
Kanamycin	500
Oxacillin	500
Tobramycin	100
Vancomycin	1000

*Administered volume should not exceed 20 microliters in dogs or cats and should not exceed systemic dose in exotic animals.

CHAPTER 250

Ocular Immunotherapy

STEVEN R. HOLLINGSWORTH, *Davis, California*

Owing to the fragility of intraocular structures and the need to maintain transparent optical media, control of ocular immunologic responses is arguably the most important aspect of ocular therapeutics. Over the last 25 years, an impressive array of medications has become available for this purpose. Although all of these agents have in common the ability to modulate the immune response of the eye, they are significantly different with regard to mode of action, site of action, route of administration, penetrability, and side effects. Proper management of ophthalmic disease requires a thorough understanding of these characteristics to select the most appropriate treatment for a specific patient.

Ocular immunotherapeutic agents may be administered by three routes: topically, subconjunctivally, or systemically (also see Chapter 249). Topical medications have the advantage of achieving high ocular tissue levels without significant systemic drug exposure. However, they are effective only against conditions involving the conjunctiva, cornea, nasolacrimal drainage apparatus, and (for some drugs) anterior uvea. Because of the biphasic anatomic character of the cornea, bipolar acetate and alcohol preparations enjoy far greater penetration than phosphate formulations and are preferred for use with intraocular conditions. Effect of topical medications can be enhanced by increasing the frequency of application.

The subconjunctival route is used under conditions in which an immediate high level of drug delivery to the anterior segment is desired and/or in situations in which frequent topical administration is not possible. The specific formulation of the drug determines the rapidity of its effect and duration of action. Because the lipophilic epithelial barrier is partially bypassed by subconjunctival delivery, water-soluble phosphate preparations are rapidly absorbed but have a short duration of action. Conversely, acetate-based preparations are slowly absorbed but remain active for a longer period of time. Among the immunotherapeutic class of drugs, only corticosteroids are delivered via this route.

Systemically administered medications are necessary to treat diseases involving the eyelids, posterior segment, and orbit and can be a useful adjunct in anterior uveitis. These drugs as a class carry the potential of adverse systemic sequelae, including immunosuppression, gastrointestinal ulceration, and steroid-induced hepatopathy.

Ocular inflammation is initiated by noxious stimuli that trigger the release of arachidonic acid from the cell membrane by the action of phospholipase A₂. Arachidonic acid is subsequently acted on by two classes of enzymes—lipoxygenase and cyclooxygenase (COX)—to produce various inflammatory mediators known collectively as the eicosanoids. The lipoxygenase pathway produces leukotrienes, which are powerful chemotactic agents. The primary end products of the cyclooxygenase pathway are prostaglandins, which cause miosis, increased vascular permeability, and diminished platelet aggregation and compromise of the blood aqueous barrier. The COX enzymes are further subdivided into COX-1 and COX-2 isoenzymes. COX-1 is sometimes referred to as the constitutive form because its end products facilitate normal physiologic functions such as gastric mucosal protection, renal perfusion, and platelet aggregation. The COX-2 isoenzyme is known as the inflammatory form because it is released in response to noxious stimuli and results in products that mediate inflammation.

In addition to the inflammatory cascade described in the previous paragraph, the eye is the target organ for a number of relatively common disorders that are characterized by self-perpetuating autoimmune inflammation. Chief among these conditions are keratoconjunctivitis sicca (KCS), chronic superficial keratitis (“pannus”), and uveodermatologic syndrome (or VKH-like syndrome). The clinical signs associated with these syndromes are discussed elsewhere. Although the pathophysiology of these conditions is complex, each is fundamentally fueled by the activation of local T lymphocytes, which leads to recruitment of additional T lymphocytes, and elaboration of interleukin and other proinflammatory agents.

To address these processes, several immunosuppressive medications have been developed that act directly on T lymphocytes.

CORTICOSTEROIDS

Corticosteroids are the most frequently used ophthalmic antiinflammatory agents and are efficacious against surface and intraocular conditions. Corticosteroids exert their antiinflammatory effect by causing upregulation of lipocortin, a protein that inhibits phospholipase A₂ and thus decreases the release of arachidonic acid. For this reason, corticosteroids suppress the formation of eicosanoids from both branches of the inflammatory pathway. Corticosteroids may be administered topically, subconjunctivally, or systemically. Specific formulations, routes of administration, and dosages are summarized in Table 250-1.

Topical Agents

Topical preparations vary in their innate potency, their ability to penetrate an intact cornea, and therefore their ability to influence intraocular inflammation. Because they suppress the local immune response, inhibit corneal healing, and potentiate proteases and collagenases, topical steroids are *absolutely contraindicated in the presence of corneal ulceration*. Although topically applied medications generally are not associated with significant systemic side effects, chronic use of topical corticosteroids has been demonstrated to cause adrenal suppression and interfere

with regulation of diabetes mellitus (Murphy, Feldman, and Bellhorn, 1990).

Prednisolone is a moderately potent corticosteroid. For topical application it is commercially available as a 0.125% or 1% sodium phosphate solution or acetate suspension. The acetate preparation has excellent ocular penetration and at the 1% concentration is frequently the drug of choice for anterior uveitis. Dexamethasone is a highly potent corticosteroid. It is available at a concentration of 0.1% in a suspension or sodium phosphate formulation either alone or in combination with neomycin and/or polymyxin B. Because dexamethasone is available in all of these forms, it is important to know the specific formulation of an individual product before selecting it for use. For example, all of these products are excellent choices for surface conditions such as conjunctivitis, keratitis, and dacryocystitis; whereas for anterior uveitis the suspension formulation is preferred over sodium phosphate preparations because of better corneal penetration. Hydrocortisone is available for topical use combined with neomycin, polymyxin B, and usually bacitracin. Because it is significantly less potent than dexamethasone or prednisolone, its only use is the treatment of mild conjunctivitis in dogs.

Subconjunctival Agents

Corticosteroids may be administered by subconjunctival injection of a solution or suspension under the bulbar conjunctiva to treat anterior segment inflammation. Because frequent topical administration of medications

Table 250-1

Corticosteroid Agents

	Formulations	Dose*
Topical Medications		
Prednisolone	0.125% or 1% acetate suspension or sodium phosphate solution	q2-48 h, depending on severity of inflammation; usually BID to QID
Dexamethasone	0.1% suspension or ointment alone or with neomycin and polymyxin; 0.1% sodium phosphate solution or ointment	q2-48 h, depending on severity of inflammation; usually BID to QID
Hydrocortisone	1% suspension or ointment usually with neomycin and polymyxin ± bacitracin	q2-48 h, depending on severity of inflammation; usually BID to QID
Subconjunctival Medications		
Triamcinolone acetonide	2, 3, 6, 10 or 40 mg/ml injectable suspension	3-15 mg
Dexamethasone or dexamethasone sodium phosphate	2, 4, or 10 mg/ml injectable solution	0.5-1 mg
Betamethasone acetate or betamethasone sodium phosphate	3 or 6 mg/ml injectable solution	1-3 mg
Systemic Medications		
Prednisolone or prednisolone acetate or sodium succinate	5- to 20-mg tablets; 3 mg/ml oral suspension; 1 or 5 mg/ml oral syrup; 25, 50, or 100 mg/ml injectable	0.5-2 mg/kg/day PO; 2 to 4 mg/kg IM or IV
Dexamethasone or dexamethasone sodium phosphate, acetate or sodium succinate	0.25- to 4-mg tablets; 2, 4, or 10 mg/ml injectable	0.1 mg/kg/day PO; 0.2 mg/kg IM or IV
Prednisone	1- to 50-mg tablets; 1- to 5-mg/ml oral suspension	0.5-2 mg/kg/day PO

*Doses listed are those initially recommended for immunotherapy. These doses should be tapered as rapidly as clinical improvement permits.
IM, Intramuscularly; IV, intravenously.

results in drug concentrations superior to those achieved by subconjunctival injection, the primary indication for subconjunctival injections is a situation in which instillation of topical medication is problematic. Subconjunctival injections are administered after application of a topical anesthetic. The dorsolateral aspect of the bulbar conjunctiva is grasped approximately 4 to 5 mm from the limbus with fine-tissue forceps and gently elevated. Using a 25- or 27-gauge needle and a tuberculin syringe, 0.25 to 0.5 ml of drug is injected under the conjunctiva. Products intended for topical application are *not* appropriate for injection by this or any other route because of irritation caused by the preservatives in these preparations. Common corticosteroid products used for subconjunctival injections include triamcinolone, dexamethasone, and betamethasone. Triamcinolone and betamethasone are commercially available in an acetate formulation; therefore they have a longer duration of action, usually 2 to 3 weeks. Methylprednisolone acetate should be avoided for subconjunctival injection because of its tendency to form painful, granulomatous plaques. Other major disadvantages of this route of administration are the danger of globe perforation and the possibility of needing to remove the drug depot because of a change in the patient's condition.

Systemic Agents

Systemic corticosteroids are indicated in the treatment of inflammatory processes involving the eyelids, anterior uvea, choroid, optic nerve, and orbit. In addition to reaching ocular and periocular structures not reached by topical medications, systemically administered corticosteroids can also be used under conditions such as corneal ulceration. Prednisone, prednisolone, and dexamethasone are the most commonly administered systemic corticosteroids and

are available in oral or injectable forms. The adverse side effects of systemic corticosteroid administration include polyuria, polydipsia, and iatrogenic endocrinopathies.

NONSTEROIDAL ANTIINFLAMMATORY DRUGS

Nonsteroidal antiinflammatory drugs (NSAIDs) exert their effect by disrupting the COX branch of the arachidonic acid inflammatory cascade and thereby preventing prostaglandin formation. Because prostaglandins are responsible for many of the changes and clinical signs associated with anterior uveitis, they are frequently used for treatment of this malady. They are especially useful because they can be applied topically in instances such as corneal ulceration or diabetes mellitus in which topical administration of corticosteroids is contraindicated. In addition, NSAIDs frequently are used before cataract surgery to prevent miosis during surgery. NSAIDs are available for both topical and systemic use. Although systemic administration of both NSAIDs and corticosteroids is unwise, they may be used together in all other combinations of routes (i.e., one systemically and one topically or both topically). Specific formulations, routes of administration, and dosages for commonly used NSAIDs are summarized in Table 250-2.

Topical Agents

Four topical NSAIDs are currently commercially available in the United States: flurbiprofen, diclofenac, ketorolac, and suprofen. Flurbiprofen is available as a 0.03% solution and is primarily used to treat anterior uveitis. Flurbiprofen has been demonstrated to decrease aqueous outflow in dogs and therefore to contribute to an increase in intraocular pressure. Furthermore, this effect is more

Table 250-2

Nonsteroidal Antiinflammatory Agents

	Formulations	Dose
Topical Medications		
Flurbiprofen	0.03% solution	BID to QID, depending on severity of inflammation
Suprofen	1% solution	BID to QID, depending on severity of inflammation
Diclofenac	0.1% solution	BID to QID, depending on severity of inflammation
Ketorolac	0.5% solution	BID to QID, depending on severity of inflammation
Systemic Medications		
Carprofen (dogs and cats)	25-, 75-, or 100-mg caplets or tablets; 50 mg/ml injectable	4.4 mg/kg/day PO or SQ initially, then 2.2 mg/kg/day
Meloxicam (dogs and cats)	1.5 mg/ml oral suspension, 7.5- or 15-mg tablets; 5 mg/ml injectable	0.2 mg/kg PO, SQ, or IV initially, then 0.1 mg/kg/day
Deracoxib (dogs)	25- or 100-mg chewable tablets	1 to 2 mg/kg/day PO
Etodolac (dogs)	150- or 300-mg tablets	5 to 15 mg/kg/day
Ketoprofen (dogs and cats)	50-, 75-, 100-, or 200-mg capsules, 12.5-mg tablets; 100 mg/ml injectable	2 mg/kg/day initially, then 1 mg/kg/day
Ketorolac	0.5% solution	BID to QID, depending on severity of inflammation

pronounced in eyes with anterior uveitis. Because of this, *intraocular pressures should be monitored* in patients with anterior uveitis and those being treated with flurbiprofen. Similar to topical corticosteroids, flurbiprofen has been demonstrated to inhibit corneal wound healing and exacerbate herpetic keratoconjunctivitis in cats. However, flurbiprofen does not potentiate other corneal infectious agents as corticosteroids do and may be used in the presence of uncomplicated (noninfected) corneal ulcers.

Along with flurbiprofen, diclofenac is routinely used in veterinary medicine. It is available as a 0.1% solution. Numerous studies and personal experience indicate that it is a more potent intraocular antiinflammatory agent than flurbiprofen and probably comparable to prednisolone acetate. Suprofen is available as a 1% solution and is closely related to flurbiprofen. Ketorolac is commercially available as a 0.5% solution. It is most commonly used to treat allergic conjunctivitis in humans. Although not widely used in veterinary medicine, it does not appear to cause an increase in intraocular pressure as flurbiprofen does.

Systemic Agents

The primary ocular indications for most NSAIDs approved for veterinary use are perioperative analgesia in dogs. Although they may be administered orally or parentally to treat anterior uveitis, only carprofen has been specifically demonstrated to be beneficial against this condition in small animals. Anorexia, vomiting, diarrhea, melena, gastric ulcers; hepatotoxicity, renal disease, and blood dyscrasias are the most frequently reported adverse effects of systemically administered NSAIDs. Caution is especially warranted with concomitant use of systemically administered corticosteroids because of the possibility of exacerbating hemorrhagic gastrointestinal problems.

Carprofen is the most frequently administered systemic NSAID in small animal practice and is a COX-2-specific inhibitor. It is available in injectable and oral forms. When given preemptively, it reduces aqueous flare in dogs with experimentally induced anterior uveitis. This has led to its common use as a treatment for this condition. In general, carprofen can be safely used in cats, but careful dose selection and patient monitoring are advisable because severe gastrointestinal side effects have been reported.

Several systemically administered NSAIDs such as meloxicam, deracoxib, etodolac, and ketoprofen have become available in the last few years. Meloxicam and deracoxib are COX-2-preferential or COX-2-specific

inhibitors. The primary ocular indication for all of these medications in small animal patients is anterior uveitis, although their efficacy has not been experimentally demonstrated. Etodolac has been associated with causing severe and irreversible decrease in tear production in dogs; thus tear production should be monitored before and during treatment with this product (Klauss et al., 2003). Ketoprofen is approved for use in horses in the United States but has been successfully used in cats and dogs. It is a nonspecific COX inhibitor.

T CELL INHIBITORS

T cell inhibitors are indicated for autoimmune conditions characterized by T lymphocyte elaboration of proinflammatory proteins. Specific formulations, routes of administration, and dosages are summarized in Table 250-3.

Topical Agents

Cyclosporine A (CsA) is the most commonly used topical T cell inhibitor for ophthalmic conditions. CsA inhibits the action of T lymphocytes in two ways. First, CsA enters T lymphocytes and blocks transcription of ribonucleic acid, which is necessary for production of interleukin-2. Second, CsA obstructs interleukin receptors on the T lymphocyte surface. In treating ophthalmic disease CsA is virtually always administered topically. It is very lipophilic and accumulates in high levels in the anterior cornea, conjunctiva, sclera, and lacrimal tissues. Because of this, CsA has been the drug of choice for KCS in dogs and is a mainstay treatment of canine chronic superficial keratoconjunctivitis (“pannus”). However, CsA penetrates into the eye poorly and is not appropriate for anterior uveal disease. Unlike topical corticosteroids, chronic use of CsA does not appear to cause significant systemic problems. It is commercially available as a 0.2% ointment and also via compounding pharmacies as a 1% or 2% suspension in various oils. When monitoring response to therapy, it is important to remember that CsA often requires 4 to 6 weeks to fully exert its effect.

Tacrolimus has a mode of action very similar to that of CsA; however, it is estimated to be 10 to 100 times more potent than CsA in vitro. Tacrolimus has been used systemically in both human and veterinary medicine for organ transplant patients, but its use has been limited because of concerns about multisystem adverse side effects. It is approved for use in an ointment form for

Table 250-3		
T Cell Inhibitory Agents		
	Formulations	Dose
Topical Medications		
Cyclosporine A	0.2% ointment, 1% or 2% suspension in oil	Typically BID; titrate based on severity of clinical signs
Tacrolimus	0.02% ointment or solution	Typically BID; titrate based on severity of clinical signs
Systemic Medication		
Azathioprine (dogs)	50-mg tablets	2 mg/kg/day PO 1 to 2 weeks, then taper

treatment of atopic dermatitis in humans. Although not commercially available, tacrolimus can be obtained as a 0.02% ointment or solution from compounding pharmacies for topical ophthalmic use. In one recent study 0.02% tacrolimus suspension administered twice daily was effective in significantly increasing tear production in dogs with KCS, even in patients that had not responded well to topically applied CsA (Berdoulay, English, and Nadelstein, 2005). Its use against other surface inflammatory conditions has not been investigated.

Systemic Agent

Azathioprine is a systemic immunosuppressive drug that exerts cytotoxic effects on helper T lymphocytes. Its most common use in veterinary ophthalmology is the treatment of nodular granulomatous episclerokeratitis (NGE) or uveodermatologic syndrome, where it is often combined with topical and/or systemic corticosteroids. Azathioprine is available as a tablet or injection. Bone marrow suppression is the most common side effect and is especially severe in cats. For this reason, azathioprine is usually not recommended for feline patients. Hepatotoxicity, gastrointestinal upset, and pancreatitis have also been associated with azathioprine use in dogs. Because of the potential severity of these side effects, complete blood counts and serum chemistry analysis are necessary before therapy, about 14 days after initiation of therapy, and then every 2 to 3 months during therapy.

CHAPTER 251

Ocular Neoplasia

BRADFORD J. HOLMBERG, *Stockholm, New Jersey*
MICHAEL S. KENT, *Davis, California*

Neoplasia of the eye and its associated support structures is not uncommon. Early detection and discrimination between benign and malignant tumors are necessary to determine the prognosis for ocular health, as well as for patient survival. The purpose of this chapter is to summarize the appearance, diagnosis, clinical behavior, and treatment of common ophthalmic neoplasms.

ORBITAL NEOPLASIA

Orbital neoplasia is rare in dogs and cats, accounting for less than 4% of all reported neoplasms. The most

common presenting clinical sign is exophthalmos, or anterior protrusion of the globe. Other accompanying clinical signs may include strabismus or globe displacement (typically away from the location of the tumor), protrusion of the third eyelid, epiphora, and exposure keratitis. Decreased retropulsion of the globe is consistent with a retrobulbar, space-occupying mass. Differentiation between orbital inflammation and neoplasia is critical for both treatment and prognosis and is discussed in detail elsewhere (see Section XII on Evolve). Orbital neoplasia is usually slowly progressive and nonpainful (unless significant inflammation or bone destruction is associated with the tumor) and

tends to affect older dogs (mean age of 8 years) and cats (mean age of 12.5 years).

Diagnosis of an orbital neoplasm is aided by diagnostic imaging techniques. Orbital ultrasonography is frequently inadequate. Computed tomography (CT) is very useful with osseous tumors or those affecting the bone (Fig. 251-1), whereas magnetic resonance imaging (MRI) is the imaging modality of choice when a soft-tissue mass is suspected. Ultrasonography is valuable for guidance of a fine-needle aspiration or nonsurgical biopsy of orbital masses since it allows visualization of the globe and mass and minimizes inadvertent globe puncture.

Approximately 75% to 91% of orbital neoplasms in dogs and 88% in cats are malignant. In dogs these tumors tend to be primary neoplasms, with osteosarcoma, multilobular osteosarcoma, and fibrosarcoma most frequently diagnosed. Secondary tumors in the orbit are much less common; but when present they usually arise from adjacent structures, including the nose, sinuses, oral cavity, and orbital glands. Nasal adenocarcinoma is the most common secondary orbital neoplasm in dogs. Cats do not follow this trend. Although primary orbital melanoma and squamous cell carcinoma have been reported in the cat, they are more likely to have secondary tumor involvement in the orbit, including fibrosarcoma, undifferentiated sarcoma, adenocarcinoma, and lymphoma. Only 14% of orbital neoplasia in cats is primary and, when present, usually represents squamous cell carcinoma, which may invade bone.

Because of the malignant behavior of most orbital neoplasms in dogs and cats, prognosis is poor. Determination of the prognosis in dogs is improved through either CT

or radiography. However, skull radiographs are much less sensitive in identifying bone invasion. The presence of osteolysis of any of the orbital bones carries a worse prognosis. Mean survival time in dogs with osteolysis was 5.1 months versus 18.6 months for those without osteolysis. Considering all orbital tumors, approximately 50% of dogs were dead within 6 months, 1-year survival rate was 19%, and mean survival time was 10 months. The prognosis for cats with orbital neoplasia is grave, with survival times at only 1 to 2 months following diagnosis. An exception is nasal lymphoma, for which a median survival of 2 years has been reported with radiation therapy.

Because of the high morbidity associated with orbital neoplasia, treatment must be aggressive and initiated relatively early in the course of disease. When possible, surgical excision of primary tumors via orbitectomy or orbitotomy is the treatment of choice and may be curative. However, the extensive nature of the mass and proximity to the brain usually make surgery difficult or contraindicated. Imaging with either CT or MRI helps to determine if surgery is feasible and to plan the extent of surgery. Tissue margins should be inked for submission to a pathologist. If evaluation of the surgical margin reveals that residual tumor has been left behind, either additional surgery or possibly radiation therapy is in order to obtain better local control of the tumor.

ADNEXAL NEOPLASIA

Neoplasia of the eyelids is observed frequently in dogs but rarely in cats. Adnexal tumors may involve the palpebral skin with or without affecting the eyelid margin. Depending on the location of the mass, eyelid function may be disrupted, resulting in loss of the normal tear film and signs associated with exposure keratitis. In addition, if the mass contacts the cornea, it may irritate the surface and potentially result in corneal ulceration. Fortunately approximately 90% of eyelid neoplasms in dogs are benign, with meibomian adenomas, melanomas, and papillomas most common. Although 25% of these masses appear malignant on histologic evaluation, metastasis is rarely reported. Older, purebred dogs are commonly affected. Diagnosis of these masses is usually made based on clinical appearance, although a fine-needle aspirate or biopsy can be performed for larger or atypical-appearing masses. Treatment is surgical. The mass may be removed by a wedge resection, carbon dioxide laser, or a combination of sharp dissection and cryotherapy. Recurrence is uncommon but may occur if excision is not complete. Growth of new masses at different sites along the eyelids is common and should not be considered as recurrences. Less common adnexal neoplasms include histiocytoma, malignant melanoma, adenocarcinoma, basal cell carcinoma, mast cell tumor, squamous cell carcinoma, and hemangiosarcoma. Of these, malignant melanoma and mast cell tumors are reported to metastasize. Treatment involves wide surgical excision using an appropriate blepharoplastic technique, with ancillary therapy as dictated by the size and type of tumor. Prognosis varies significantly, depending on the type of tumor. Systemic staging of patients with malignant melanoma or mast cell tumors should be completed. Adjuvant therapy with

Fig. 251-1 Axial computed tomography (CT) image of an orbital osteosarcoma in a dog that presented with conjunctivitis and swelling along the left zygomatic arch. The CT reveals osteolysis along with marked periosteal reaction of the orbital bones.

carboplatin for malignant melanoma and with lomustine (CCNU) and/or vinblastine along with prednisone can be used to treat possible metastasis of mast cell tumors (see Chapter 65).

Squamous cell carcinoma is the most common eyelid tumor in cats. Most affected cats are older and lack periocular pigmentation. These tumors are suspected to be associated with ultraviolet light exposure. Cats are presented with either a proliferative pink-to-white mass with a “cobblestoned” surface or an ulcerative lesion that destroys the eyelid margin (Fig. 251-2). This tumor is frequently mistaken as bacterial or traumatic blepharitis or as an eosinophilic granuloma; therefore appropriate treatment is often delayed, resulting in large tumors that are difficult to manage. The presence of an ulcerated mass on the eyelid always warrants further examination, including cytology and/or biopsy. Adnexal squamous cell carcinoma has the potential to invade the orbit or to metastasize to regional lymph nodes, both of which carry a poor prognosis. However, early surgical excision, sometimes with adjunctive therapy, may be curative. Superficial squamous cell carcinoma of the eyelid margin may be responsive to strontium-90 β -therapy. Other palpebral neoplasms in cats include mast cell tumor, basal cell carcinoma, fibrosarcoma, spindle cell sarcoma, and apocrine hidrocystoma. Although these masses can be expansile and disrupt the eyelid margin, they tend not to metastasize. Recurrence is common without complete excision.

The biologic behavior of mast cell tumors on the eyelids of cats and dogs is poorly defined, although metastasis has been confirmed in several clinical cases.

SURFACE OCULAR NEOPLASIA

Of all ocular neoplasia, tumors of the conjunctiva, third eyelid, and cornea are the least common. Dermoids are congenital tumors derived from ectoderm and mesoderm. They usually involve the lateral limbus but may also affect the eyelid margin or third eyelid. They have the

Fig. 251-2 Squamous cell carcinoma of the central aspect of the lower eyelid of a cat. Note the ulcerated appearance and local destruction of the eyelid margin.

characteristic appearance of haired skin. Breeds most commonly affected include the dalmatian, dachshund, Doberman, German shepherd, and Saint Bernard dogs and Burmese cats. Although benign, they may become irritating locally and therefore should be removed by superficial keratectomy and conjunctivectomy. Excision is curative provided all hair follicles are removed. Another benign tumor frequently arising at the dorsolateral limbus of dogs and cats is the epibulbar or limbal melanocytoma. German shepherds and Labrador retrievers are predisposed. In both cats and dogs these tumors can be locally expansile, potentially extending through the corneal stroma and entering the anterior chamber. In young dogs these tumors progress more rapidly and require removal using partial- to full-thickness keratectomy/sclerectomy. Adjunctive therapy following partial keratectomy has included cryotherapy, β -irradiation, and laser photoablation. Although strontium-90 radiotherapy used as adjuvant treatment is effective, with only one reported recurrence in a series of 30 dogs, acute and late side effects, including corneal scarring, corneal vascularization, conjunctivitis, lipid keratopathy, localized bullous keratopathy, deep scleral thinning, and scleral perforation were seen in 63% of cases. Metastasis has not been reported in dogs or cats. Before diagnosing a pigmented mass at the limbus as a limbal melanocytoma, a thorough ophthalmic examination is recommended to ensure that the mass does not represent extrascleral extension of an intraocular melanoma, which may carry a more serious prognosis.

Conjunctival neoplasia is quite rare in dogs and cats. Reported tumors include hemangioma, hemangiosarcoma, mast cell tumor, lymphoma (primary or metastatic), squamous cell carcinoma, and papilloma. Complete excision with or without adjunctive therapy is usually curative. Two exceptions include malignant melanoma in both the dog and cat and systemic histiocytosis in the dog. Conjunctival melanoma appears as a raised, irregular, melanotic mass on the bulbar, third eyelid, or palpebral conjunctiva (Fig. 251-3). Although usually small in size, they can be locally aggressive and invasive. Metastasis to the regional lymph nodes (cats) and the orbit, pulmonary parenchyma, and liver (dogs) has been reported. Treatment includes surgery, but other

Fig. 251-3 Raised melanotic mass along the lateral bulbar conjunctiva of a dog. Biopsy was consistent with a melanoma.

local therapy such as irradiation with strontium-90 should be considered since clean surgical margins have rarely been obtained in reported clinical cases.

Malignant histiocytosis has a predilection for Bernese mountain dogs. Frequently affected dogs demonstrate severe chemosis secondary to a subconjunctival infiltrate. Exophthalmos, episcleral nodule formation, corneal edema, uveitis, and retinal detachment may also be present. The signalment and clinical signs are suggestive of the diagnosis, and it is confirmed by biopsy of the subconjunctiva. Although the ocular signs may appear first, the systemic nature of this disease and its poor response to medical therapy usually result in euthanasia. However, a recent report has indicated that treatment with lomustine may be effective at helping control this disease.

Neoplasia of the third eyelid or nictitating membrane is uncommon. Depending on the extent and location of the mass, the clinical appearance varies. Large masses at the base of the third eyelid, particularly those affecting the gland of the third eyelid, tend to result in third eyelid protrusion and exophthalmos with or without lateral displacement of the globe. By contrast, large masses on the anterior face of the third eyelid tend to cause enophthalmos. Discrete tumors on the surface or leading edge of the third eyelid are usually easily recognized by their altered color and contour. Retropulsion of the globe allows examination of almost the entire third eyelid (except for the orbital aspect) and greatly facilitates diagnosis of a third eyelid tumor. The behavior of third eyelid neoplasms differs significantly between dogs and cats, with most neoplasms benign in dogs but malignant in cats.

Adenocarcinoma of the gland of the third eyelid is the most common third eyelid tumor in dogs. Over 50% of these tumors recur without complete excision but rarely metastasize. Therefore removal of the entire third eyelid is recommended and frequently achieves a cure. Other reported third eyelid tumors in dogs include hemangiosarcoma, lobular adenoma, and squamous cell carcinoma. Surgical excision with or without ancillary therapy has been effective. Melanoma of the third eyelid in dogs is not benign and behaves similarly to conjunctival melanomas previously described.

As for the upper and lower eyelids, squamous cell carcinoma is the most common neoplasm of the third eyelid of cats. Treatment and success of therapy depend on extent of tumor involvement. Tumors that only involve the third eyelid can be managed successfully by complete excision of the third eyelid. However, because metastasis to the orbit is possible, staging should be completed before surgery. Unlike dogs, feline third eyelid adenocarcinomas have been demonstrated to metastasize to the lungs, liver, and kidneys. Other reported malignant (primary or secondary) third eyelid tumors in cats include fibrosarcoma and lymphoma. Presence of third eyelid neoplasia in cats warrants a complete systemic workup, including three-view thoracic radiographs and abdominal ultrasound, since most tumors are invasive and have the potential to metastasize. One exception is hemangiosarcoma, which appears to behave in a benign fashion and for which surgical removal is usually curative.

INTRAOCULAR NEOPLASIA

Intraocular tumors in dogs and cats occur sporadically and are usually secondary findings on the clinical examination. Animals may present with glaucoma, hyphema, corneal edema, buphthalmos, dyscoria, uveitis, retinal detachment, and/or blindness. Observation of a change in contour of the iris surface or alteration in iris color may be early signs of an intraocular mass (Fig. 251-4). In both dogs and cats anterior uveal melanoma is unquestionably the most frequently diagnosed intraocular neoplasm. The appearance and behavior of this tumor differs dramatically between species. In dogs these tumors are usually solitary, nodular, darkly pigmented, and benign. Most affected dogs are older, with golden and Labrador retrievers, boxers, and German shepherds predisposed. Eighty-two percent of intraocular melanomas in dogs are benign, with a 0% metastasis rate. The rest (18%) are considered malignant melanomas based on histologic appearance and mitotic index. However, biologically most canine intraocular melanomas behave in a benign fashion, with a metastatic potential of only 4% to 6%. Systemic staging, including three-view thoracic radiographs and abdominal ultrasound, are warranted in patients having tumors with a high mitotic index or other indicators of malignancy. Treatment is based on the size of the tumor and presence of complicating secondary factors. Some focal tumors can be ablated or reduced in size using a diode laser. Larger tumors or those compromising the overall health of the eye are treated by enucleation. In cases of malignant melanoma with evidence of metastasis, systemic chemotherapy with an agent such as carboplatin may be considered.

Anterior uveal melanomas in cats carry a worse prognosis than those in dogs. The majority of these tumors are considered malignant, although the time or stage at which they metastasize is unknown and controversial. Cats usually present with focal- to-multifocal areas of iris hyperpigmentation known as *nevi* or *freckles*. The masses are usually not raised but may take on a velvety appearance (Fig. 251-5). Diagnosis is made based on clinical appearance, and the owner should be informed of the

Fig. 251-4 Intraocular melanoma in a dog presenting as a focal, raised, pigmented mass arising from the surface of the iris and resulting in dyscoria.

Fig. 251-5 Diffuse iris melanoma in a cat. Note the lack of a defined mass, but instead multifocal areas of iridal hyperpigmentation. Mild dyscoria is present, potentially indicating aggressive tumor involvement.

metastatic potential. Two-year survival rates for cats with tumor in the iris only were 100%. However, microscopic evidence of extension to involve the ciliary body reduced this to 80%, and with scleral involvement the 2-year survival rate was 20%. Treatment is enucleation, preferably early to prevent metastasis. Clinical signs that suggest that the tumor is aggressive and that enucleation should be performed include dyscoria, glaucoma, uveitis, and the presence of free-floating tumor cells within the aqueous humor.

Other primary intraocular tumors in dogs include ciliary body adenocarcinoma and medulloepithelioma. Iridociliary adenocarcinomas, despite their histologic description, tend to be biologically benign and have a predilection for golden and Labrador retrievers. Medulloepitheliomas are embryologic neuroepithelial tumors usually arising in the ciliary body of young dogs. Although both of these tumors are benign, they are locally invasive and destructive and usually require enucleation.

Cats that receive penetrating trauma to the eye, especially if lens capsule rupture has occurred, are predisposed to the development of posttraumatic sarcoma. The origin of this tumor is debatable, although some tumors express collagen type IV and crystalline α -A, which is consistent with a lens capsule epithelium origin. These tumors are extremely aggressive and destructive, rarely respecting the scleral boundaries. Unfortunately, by the time the tumor has been detected, extraocular extension usually has occurred. The tumor frequently courses along the optic nerve toward the brain, resulting in a mortality rate of over 90%. Treatment is effective only if there is early detection followed by early enucleation. For this reason blind eyes of cats that have experienced trauma should always be removed as early as possible.

Although almost any neoplasm can metastasize to the eye, the most common secondary intraocular tumor in dogs and cats is lymphoma. Most animals initially present with anterior uveitis with notable cellular exudate in the anterior chamber (hypopyon). Cats may have obvious iridal nodule formation or clusters of fibrinohemorrhagic debris in the anterior chamber (Fig. 251-6). Although there

Fig. 251-6 Large fibrinohemorrhagic clot within the anterior chamber of a cat with multicentric lymphoma. Numerous neoplastic lymphoblasts were identified during cytologic evaluation of an aqueous humor aspirate.

are many causes of uveitis in dogs and cats (see Chapter 262), these patients are excellent examples of why a thorough diagnostic investigation of all patients with uveitis is warranted. If lymphoma is identified as the cause of uveitis in these patients, not only can specific rather than empiric therapy be initiated, but there is a greater opportunity to extend the patient's quality and length of life. If a thorough systemic diagnostic investigation does not yield an etiologic diagnosis in a patient with uveitis suspected to be caused by lymphoma, aqueocentesis is indicated. Treatment for intraocular lymphoma includes topical application of 1% prednisolone acetate ophthalmic suspension, which will decrease the uveitis, along with systemic chemotherapy with a "CHOP-based" protocol (see Chapters 65 and 72), which often result in remission and resolution of ocular and extraocular clinical signs. Most cases of ocular lymphoma respond very favorably to topical and systemic therapy, if secondary sequela (glaucoma, iris bombé, cataract, retinal detachment) do not occur. Median survival times for dogs and cats with multicentric lymphoma treated with chemotherapy are reported to be about 1 year and 6 months, respectively. Secondary (metastatic) intraocular tumors other than lymphoma do not usually respond to medical therapy, and secondary complications typically ensue. Symptomatic therapy with antiinflammatory and antiglaucoma medications to improve ocular comfort typically is necessary. Surgery (enucleation) is palliative but is rarely performed because of the patient's overall systemic health.

CHAPTER 252

Corneal Colors As a Diagnostic Aid

DAVID J. MAGGS, *Davis, California*

The cornea is optically transparent; it is the major refractive structure of the eye, richly innervated, and the ocular structure most obvious to the owner. As such it is a physiologically fragile, visually critical, highly sensitive, and easily observed ophthalmic tissue and therefore frequently is the reason for presentation of a small animal to a veterinarian. For this reason, correctly interpreting corneal pathology is critical for diagnosing not only corneal disease but many other ocular and some systemic diseases. Fortunately corneal pathology is frequently visible as a characteristic corneal color change or loss of corneal clarity. Common pathologic responses within the cornea include vascularization, edema, scarring, lipid and/or mineral deposition, pigmentation, and inflammatory cell infiltration. These changes frequently are seen in various combinations. Each of these pathologic changes is associated with a defining color change. Because some of the colors are similar, an appreciation for the “texture” or other character of these changes is also important. Learning to recognize and interpret these color changes and the mechanisms responsible for them provides a simple and logical approach to diagnosis of all corneal and some intraocular diseases. Such understanding also facilitates selection of appropriate diagnostic tests. This

chapter is designed to assist the general practitioner in the interpretation of corneal color changes.

RED AND LINEAR

Corneal vascularization causes a red discoloration of the cornea and is a nonspecific indication of chronic inflammatory disease. However, distribution of corneal blood vessels provides valuable information regarding location and depth of the inciting cause (i.e., blood vessels reveal not *what* the inciting cause is but *where* it is). Therefore differentiation of deep from superficial corneal vascularization is critical for selection of further diagnostic steps and for differentiation of vision-threatening intraocular disease from irritating surface ocular disease (Fig. 252-1). Superficial corneal vessels arise from the conjunctiva at the limbus. They tend to be fine, branch dichotomously to form “tree-shaped” patterns on the cornea, and can be seen crossing the limbus (Fig. 252-2). Superficial vessels reflect surface ocular disease caused by inadequate protection (from the eyelids or tear film) or excessive frictional irritation of the corneal surface (by an exogenous or endogenous influence). Although a large list of potential causes should be considered, the diagnostic testing required to

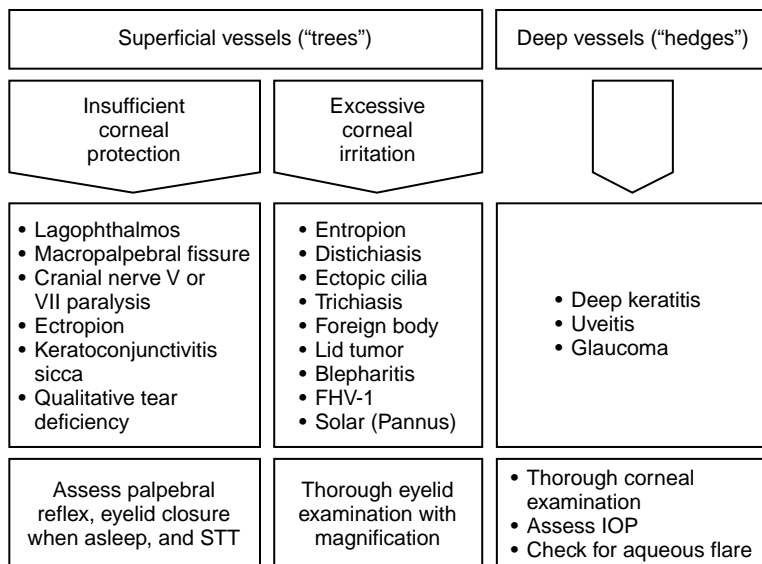

Fig. 252-1 Causes of and diagnostic steps for corneal vascularization, which causes red "linear" discoloration of the cornea. CN, Cranial nerve; KCS, keratoconjunctivitis sicca; FHV-1, feline herpesvirus type 1; STT, Schirmer's tear test; IOP, intraocular pressure.

Fig. 252-2 Superficial corneal vessels. Note that they cross the limbus, branch, and appear "tree-like." They indicate superficial or "surface" corneal disease. (Courtesy University of California Davis Veterinary Ophthalmology Service.)

Fig. 252-3 Deep corneal (stromal) vessels in a cat with a deep ulcer. Note that the blood vessels do not cross the limbus or branch and appear more "hedge-like." They indicate deep corneal (stromal) or intraocular disease. Note also the stromal white blood cells within the ulcer bed producing a yellow-green discoloration. (Courtesy University of California Davis Veterinary Ophthalmology Service.)

differentiate these is simple (see Fig. 252-1). Deep corneal vessels arise from perilimbal ciliary and scleral vessels; tend to be darker, shorter, and straighter; and tend not to branch overtly (Fig. 252-3). They cannot be seen crossing the limbus but instead arise from under the scleral shelf. They form a "hedge-shaped" pattern on the cornea. They are characteristic of serious, vision-threatening diseases such as deep keratitis, uveitis, or glaucoma, which require similarly straightforward tests but different from those suggested by superficial corneal vessels (see Fig. 252-1).

BLUE AND "FLUFFY"

Corneal edema is usually evident as a bluish discoloration of the cornea, often in a "fluffy" or "ground glass" pattern (Fig. 252-4). Although the edema accumulates in the collagenous corneal stroma, it occurs as a result of dysfunction of one or both of the cell layers responsible for corneal deturgescence—the epithelium or endothelium. Application of fluorescein stain and careful attention to the severity and area of edema will suggest which cell

Fig. 252-4 Corneal edema causes a blue and "fluffy" corneal discoloration. This dog has a deep and malacic ("melting") ulcer. (Courtesy University of California Davis Veterinary Ophthalmology Service.)

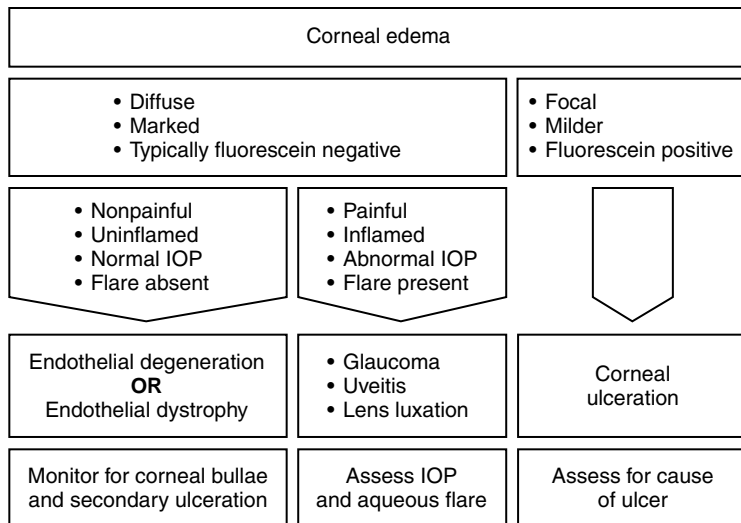

Fig. 252-5 Causes of and diagnostic steps for corneal edema. *IOP*, Intraocular pressure.

layer is more likely dysfunctional (Fig. 252-5). Epithelial loss (corneal ulceration) produces more focal and milder edema in close spatial association with a fluorescein-positive area of cornea. Endothelial decompensation tends to produce more severe and diffuse corneal edema because endothelium has the more important role in maintaining deturgescence. Endothelial dysfunction may occur as a primary event, especially in dogs. Primary endothelial dystrophy is relatively common in Boston terriers and Chihuahuas, whereas senile endothelial degeneration might be suspected in older dogs of any breed. Unless ulceration occurs secondary to corneal bullae (blister) formation, these primary endothelial diseases are characteristically nonpainful, and the cornea does not retain fluorescein. Secondary endothelial decompensation occurs in dogs and cats with uveitis, glaucoma, anterior lens luxation, or scleritis and is associated with ocular pain, inflammation, and other specific abnormalities. Because domestic (outbred) cats are less prone to primary inherited disease and the feline endothelium seems more resistant to senile changes, diffuse corneal edema in cats is usually secondary to these more serious intraocular diseases and warrants urgent and complete examination. An exceptional disease that seems peculiar to cats in which corneal edema is the major sign is feline acute bullous keratopathy. This tends to occur in younger cats without any recognized predisposing cause or history. The onset of massive stromal edema and sometimes rupture can occur within hours! The pathogenesis is proposed to involve the stroma itself rather than the endothelium. Treatment involves emergency conjunctival grafting.

GRAY AND WISPY

Corneal scars are caused by derangement of the usual highly regular array of stromal collagen. The scattering of light this induces causes gray, wispy discolorations in an uninflamed cornea (Fig. 252-6). These lesions do not retain fluorescein stain. Scars are by definition inactive and require no further treatment. Presence of inflammatory signs such as vascularization or cellular infiltrates in association with scarring suggests continuing active inflammation.

Fig. 252-6 Corneal fibrosis (scarring) evident as a generalized gray and “wispy” discoloration of the cornea. There are also superficial corneal blood vessels and corneal melanosis present. (Courtesy University of California Davis Veterinary Ophthalmology Service.)

WHITE AND “SPARKLY” OR “CREAMY”

Subepithelial accumulation of lipid and/or mineral in the anterior stroma appears as sparkly, crystalline, or more coalescing creamy or shiny areas of white discoloration. These accumulations frequently contain cholesterol and/or calcium; however, varying combinations of lipids and minerals are possible. The clinician's major goal following identification of this characteristic change is to determine if the lipid/mineral accumulation represents a primary or secondary disease (Fig. 252-7). Corneal lipid dystrophy describes a primary inherited, but not necessarily congenital, condition that occurs in many dog breeds but rarely in cats. Corneal lipid dystrophy is usually bilateral and approximately symmetric, with lipid usually deposited in the central or paracentral cornea, often in a circular or elliptical shape (Fig. 252-8). Because the lipid deposits typically are subepithelial, the cornea is usually negative to fluorescein stain retention and patients appear nonpainful. However, occasionally the overlying epithelium ulcerates. The disease may be slowly progressive but has minimal effect on vision and requires no therapy. Commonly affected breeds include the Siberian husky, Samoyed, bichon frise, and cavalier King Charles spaniel.

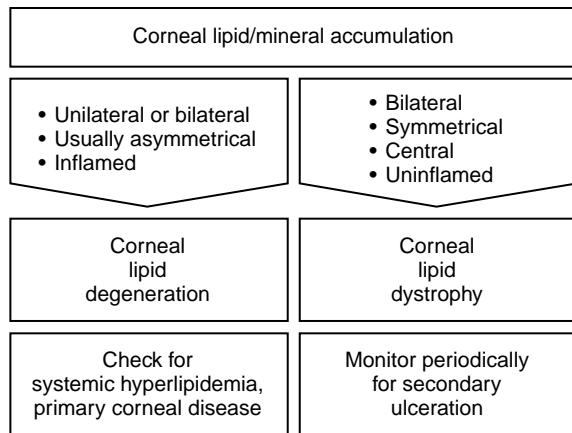

Fig. 252-7 Causes of and diagnostic steps for corneal accumulation of lipid and/or mineral, which causes white “creamy” or “sparkly” discoloration of the cornea.

Fig. 252-8 Corneal lipid dystrophy. The other eye of this dog was similarly affected. (Courtesy University of California Davis Veterinary Ophthalmology Service.)

Alternatively, lipid may accumulate secondary to corneal inflammation or injury in dogs or rarely cats. In these cases it is termed corneal degeneration, is usually unilateral, and frequently is associated with inflammation evident as coincident corneal edema or vascularization (Fig. 252-9). These lesions are frequently seen in animals with chronic uveitis, especially with long-term corticosteroid use. Typically there will be a history of ocular trauma, often with ulceration that healed with vascularization and subsequent lipid deposition. However, some animals deposit lipid in their cornea without evidence of prior trauma. These animals usually develop a sparkly-to-creamy, sometimes vascularized band of perilimbal corneal lipid as a result of elevated serum lipid. Investigation of common causes of systemic hyperlipidemia such as hypothyroidism, diabetes mellitus, hyperadrenocorticism, or primary hyperlipidemia is essential in such animals. Serum triglycerides and cholesterol should both be measured.

BLACK AND GEOGRAPHIC (“MAP-SHAPED”)

Corneal pigmentation causes an obvious black discoloration of the superficial (epithelial and anterior stromal) cornea. In dogs the pigment is melanin and

Fig. 252-9 Corneal lipid degeneration in a dog. Note the cream-to-sparkly white discoloration with associated corneal vascularization. (Courtesy University of California Davis Veterinary Ophthalmology Service.)

Fig. 252-10 Corneal melanosis in a dog. Note the superficial corneal blood vessels, which are a common finding with corneal melanin since they share the same mechanism. (Courtesy University of California Davis Veterinary Ophthalmology Service.)

tends to encroach insidiously from the limbus (Fig. 252-10). Heavily pigmented dogs, especially Pekingese, pugs, and chow-chows, seem to be more prone to this change (sometimes called “pigmentary keratitis”). In sharp contrast, black discoloration of the feline cornea is rarely caused by melanin. Instead the feline corneal pigment is soluble and appears to originate from or be spread in the tear film. It may also cause black tear staining of the periocular skin and can be deposited in the corneal stroma. In the latter case it is usually associated with an area of necrotic, sequestered stromal collagen and is called a “corneal sequestrum” (Fig. 252-11). Regardless of pigment type or species affected, corneal pigmentation (like the superficial corneal blood vessels that often accompany it) is a sign of chronic irritation. Like corneal vascularization, pigmentation of the cornea provides no information regarding nature of the specific irritant but does accurately direct attention to the location of the irritation (Fig. 252-12).

TAN AND “GREASY”

Fibrin and white blood cells are commonly seen together and appear as a tannish-gray corneal discoloration. They appear in two common locations, each with characteristic appearance. Keratic precipitates (KPs) are multiple,

Fig. 252-11 Corneal sequestrum in a cat with feline herpesvirus. Sequestra can vary from amber to dark black and are caused by a soluble pigment. (Courtesy University of California Davis Veterinary Ophthalmology Service.)

Fig. 252-13 Keratic precipitates are present on the corneal endothelium of this cat with anterior uveitis. The larger darker discolorations are small clumps of hemorrhage (hyphema). (Courtesy University of California Davis Veterinary Ophthalmology Service.)

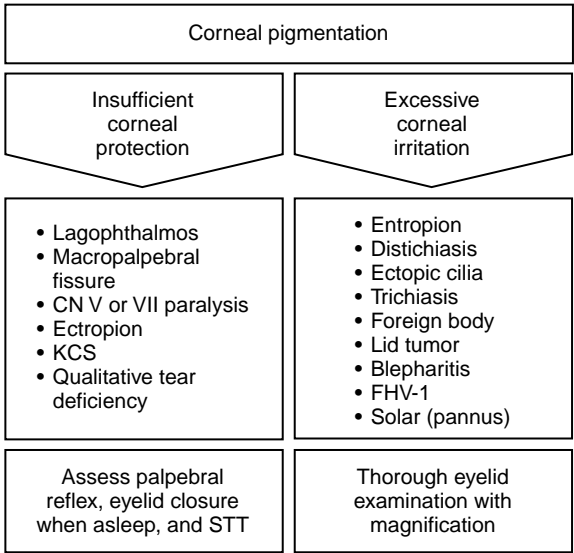

Fig. 252-12 Causes of and diagnostic steps for corneal pigmentation (melanosis or sequestration), which causes a black geographic discoloration of the cornea. CN, Cranial nerve; KCS, keratoconjunctivitis sicca; *FHV-1*, feline herpesvirus type 1; *STT*, Schirmer's tear test.

Fig. 252-14 This dog has a ruptured cornea. This is visible as a greasy tan area axially backlit (retroilluminated) here by the tapetal reflection. There is some surrounding (bluish) corneal edema, intraocular hemorrhage (hyphema), and some iris melanin remnants against the anterior lens capsule. This was the result of a cat claw injury. (Courtesy University of California Davis Veterinary Ophthalmology Service.)

clumped accumulations of inflammatory cells and fibrin on the inner corneal (endothelial) surface (Fig. 252-13). They have a greasy appearance, sometimes termed *mutton fat*, and tend to be deposited most densely on the ventral cornea. KPs are a pathognomonic sign of uveitis, and the causes of uveitis should be thoroughly investigated (see Chapter 262). A ruptured globe with prolapsed uvea (a “staphyloma”) will also produce a greasy tan discoloration of the usually central cornea (Fig. 252-14). This indicates ulcerative or traumatic perforation. The surrounding corneal health is usually poor (e.g., malacic, edematous, vascularized, infiltrated with white blood cells). The protruding uvea (iris) is coated in a layer of fibrin and inflammatory cells and therefore has a tanish-brown appearance. A staphyloma frequently appears as a raised area in the center of an otherwise deep ulcer.

YELLOW-GREEN

Inflammatory cell infiltration of the corneal stroma is termed *stromal keratitis* or (when the epithelium is intact) a *stromal abscess*. These conditions cause a yellow-green discoloration characteristic of pus elsewhere in the body (see Fig. 252-3). This usually occurs in response to an infectious etiology; however, nonseptic infiltration of the cornea can occur. Inflammatory cells originate from the tear film, limbus, and sometimes the uveal tract and can accumulate within the cornea surprisingly quickly, indicating a potent chemotactic stimulus. This is most often caused by an infection, blunt trauma (corneal contusion), or an intracorneal foreign body. Therefore corneal cytology along with culture and sensitivity testing should be performed, and broad-spectrum antibiotic therapy initiated promptly. Frequent reexamination of the cornea is essential because liberation of lytic enzymes by the inflammatory cells (and any associated bacteria) can cause rapid collagenolysis or corneal “melting.”

Table 252-1

Recommended Diagnostic Tests Based on Corneal Color Changes

Color	Histology	Mechanism	Recommended Tests
Red	Blood vessels	Chronic irritation	Fluorescein stain, STT, palpebral and corneal reflexes
"Fluffy" blue	Stromal edema	Endothelial or epithelial dysfunction	Fluorescein stain, IOP, flare, check for lens luxation
"Wispy" gray	Stromal scar	Previous (inactive) inflammation	Fluorescein stain
"Sparkly" white	Lipid/mineral accumulation	Dystrophy, degeneration, or hyperlipidemia	Fluorescein stain, systemic lipid analyses
Black	Pigmentation	Chronic irritation	Fluorescein stain, STT
"Punctate" tan	KPs or staphyloma	Uveitis	Palpebral and corneal reflexes
Yellow-green	Inflammatory cell infiltration	Inflammation (usually septic)	IOP, flare, systemic disease testing
			Fluorescein stain, cytology, culture and sensitivity testing, PCR

IOP, Intraocular pressure; PCR, polymerase chain reaction; STT, Schirmer's tear test.

DIAGNOSTIC TESTING FOR CORNEAL DISEASE

Knowledge of the mechanisms by which these seven corneal color changes occur can be used to direct diagnostic testing as suggested in Table 252-1. The most commonly used tests for investigation of corneal pathology are

Schirmer's tear test, fluorescein and/or rose bengal staining, tonometry, assessment of aqueous flare, and corneal cytologic and microbiologic assessment (see Chapter 248). Histopathologic examination of keratectomy samples may be required to confirm a diagnosis in some cases of proliferative or inflammatory corneal disease.

CHAPTER 253

Differential Diagnosis of Blindness

HOLLY L. HAMILTON, *Loveland, Colorado*

SUSAN A. MCLAUGHLIN, *West Lafayette, Indiana*

Blindness can result from lesions that interfere with the formation of the image by the retina, transmission of the image to the visual cortex, or interpretation of the image by the visual cortex. Numerous diseases can cause bilateral loss of vision. The usual approach to such patients involves confirmation and characterization of the visual impairment, anatomic localization of the cause, and appropriate diagnostic testing.

CONFIRMATION OF BLINDNESS

Diagnostic confirmation of blindness is the essential first step. This can be achieved by watching the animal navi-

gate in the examination room or by setting up an obstacle course. Evaluation should be performed in both bright and dim lighting. Some animals, particularly cats, will not attempt to walk in an unfamiliar environment. Observing the animal's response to noiseless objects such as cotton balls dropped across its visual field works well with animals that will not ambulate. The menace response (a threatening gesture such as a hand moving towards one eye) can be used to assess vision and should elicit rapid eyelid closure, provided that the facial nerve (CN VII) is intact. Care must be taken when testing the menace response not to stimulate the trigeminal nerve by touching the animal or by creating air currents since such stimuli can induce a

palpebral reflex (via CN V and CN VII). A Plexiglas shield or vertical hand movements prevent air currents when testing the menace response. The visual placing reaction may also be used to assess vision. The animal is held without restricting the forelegs and advanced toward a table. If the animal sees the table, it will reach out towards the table edge using the front legs.

Pupillary Light Reflex

The pupillary light reflex (PLR) provides valuable information about visual pathways but does not test vision. The PLR should be evaluated in a darkened room with a bright, focal light source. The direct (constriction of the stimulated pupil) and consensual (constriction of the unstimulated pupil) PLR should be evaluated. Absence of a direct and consensual PLR in a blind animal is consistent with (but not pathognomonic for) a lesion in the subcortical visual pathway, which includes the retina, optic nerve, optic chiasm, and optic tract. However, abnormal direct and consensual PLRs also can occur (with or without blindness) as a result of bilateral dysfunction of the efferent pathway such as synechia (iris adhered to lens or cornea), iris atrophy, topical mydriatic application, or oculomotor nerve (CN III) deficits. A frightened or nervous animal may have notably reduced PLRs because of stimulation of the iris dilator muscle by the sympathetic nervous system. Therefore, when a reduced or absent PLR is encountered, it should be reassessed later in the examination once the animal becomes more accustomed to the surroundings. Bilateral lesions in the lateral geniculate nucleus, optic radiation, or visual cortex, often referred to as central or intracranial blindness, cause loss of sight without affecting the PLR. The presence of a PLR also does not absolutely exclude blindness secondary to retinal disease. Some cases of retinal degeneration or retinal detachment are severe enough to cause blindness but not completely prohibit a PLR.

In this chapter the causes of blindness are grouped according to the affected region of the visual pathway. Disorders are discussed in the order in which they would typically be encountered during an ophthalmic examination. When blindness is confirmed in a patient without ocular abnormalities, additional diagnostic tests are required. In addition, even if an ocular cause of blindness is identified, most ophthalmic lesions are not pathognomonic for a specific etiologic agent, and additional diagnostic tests will be needed to identify the cause.

DIAGNOSTIC TESTING

Electroretinography detects and quantifies a mass retinal response to photic stimuli. The electroretinogram (ERG) primarily evaluates the outer retinal layers (especially the photoreceptors), and is severely diminished or absent with blindness caused by retinal disease (e.g., sudden acquired retinal degeneration or end-stage progressive retinal atrophy). The ERG may be normal in early glaucoma because glaucoma affects the ganglion cell and nerve fiber layers of the inner retina before the photoreceptors. An ERG can be performed in an awake or anes-

thetized animal but does require special equipment and thus is typically available only at referral centers. The ERG waveform and amplitude is affected by anesthesia, breed, age, equipment, and technique.

Visual-evoked potentials (VEPs) are used to evaluate electrical potentials in postretinal visual pathways, including the visual cortex in response to light stimulation of the eye. The potentials are recorded by scalp electrodes. The VEP is not as frequently used or as standardized as the ERG, but it can be useful in cases of blindness caused by lesions in the optic nerve, visual tracts, or visual cortex.

Ocular ultrasound is useful for evaluation of the globe in cases of opacification of the ocular media and may aid in identification of retinal detachment or intraocular mass lesions. In most animals this can be performed without sedation, using only topical anesthesia. Ultrasound is also useful for evaluation of orbital contents, especially the optic nerve, but computed tomography or magnetic resonance imaging (MRI) provide superior information regarding this structure.

When exudate within the vitreous or aqueous humor may yield potential cytologic or serologic clues, samples may be collected by centesis under general anesthesia. *Vitreous centesis* is performed using a 20- to 23-gauge needle inserted 6 to 8 mm posterior to the limbus and directed toward the posterior pole. Aspiration is performed in a slow, controlled manner, and 0.1 to 0.2 ml of vitreous should be aspirated for cytology and bacterial and fungal culture. There is some risk of hemorrhage and retinal detachment; thus this is usually performed by experienced personnel when less invasive techniques have failed to identify a cause or in permanently blind eyes. In young, normal animals, the vitreous is gel-like and difficult to aspirate. In patients with posterior segment inflammation, the vitreous becomes more liquefied and easier to aspirate. In patients with anterior segment disease, aqueous humor can be attained in a similar manner but via a limbal entry point. *Aqueous centesis* is most likely to yield positive results with cytologic evaluation in cases of suspected intraocular lymphosarcoma or in evaluation for intraocular antibody production against infectious agents such as *Toxoplasma gondii* (see Chapter 262).

OPACITY OF THE OCULAR MEDIA

The clear ocular media include the cornea, aqueous humor, lens, and vitreous. These structures are transparent to allow passage of light and image formation by the retina. Mild opacification of the ocular media results in blurred vision, and significant opacification results in blindness.

Corneal Opacification

Blindness secondary to corneal disease occurs only with bilateral, severe, diffuse corneal lesions. Typically these are severe enough to obscure the clinician's evaluation of intraocular structures. Causes of corneal opacification include infiltration of the cornea with melanin, edema, blood vessels, or inflammatory or neoplastic cells or misalignment of corneal collagen fibers (scarring). Corneal melanosis resulting from eyelid abnormalities (entropion,

ectropion, lagophthalmos, facial nerve paralysis), keratoconjunctivitis sicca, and chronic superficial keratitis (“pannus”) can result in blindness. Diffuse, severe corneal edema can occur secondary to corneal endothelial dystrophy, endothelial degeneration, endotheliitis, glaucoma, or anterior uveitis. Symblepharon (conjunctiva adhered to cornea) and inherited corneal dystrophy can also cause corneal opacification.

Aqueous Humor Opacification

Opacification of the aqueous humor typically results from accumulation of red blood cells (hyphema), white blood cells (hypopyon), lipid, or fibrin clots. These typically gravitate ventrally and only partially affect vision. However, if the anterior chamber is diffusely and severely affected to the extent that the iris and other intraocular structures are obscured, blindness may result. Hyphema occurs secondary to coagulopathies (factor deficiencies, warfarin toxicosis, immune-mediated thrombocytopenia), infectious diseases (ehrlichiosis, rickettsiosis), trauma, neoplasia, systemic hypertension, or retinal detachment. Hypopyon results from immune-mediated, neoplastic (lymphosarcoma), or infectious (blastomycosis, cryptococcosis, histoplasmosis, coccidioidomycosis, toxoplasmosis, feline infectious peritonitis, protothecosis, brucellosis, bacterial septicemia) diseases. Lipemic aqueous occurs in patients with hyperlipidemia (serum cholesterol and/or triglycerides) and concurrent blood-aqueous barrier disruption (uveitis). Hypertriglyceridemia can be primary or secondary to diabetes mellitus, hyperadrenocorticism, or hypothyroidism. A complete physical examination is indicated in any patient with opacification of the anterior chamber. Any enlarged lymph nodes, subcutaneous masses, or draining skin tracts should be aspirated for cytologic evaluation. A complete blood count, serum biochemistry profile, urinalysis, thoracic and abdominal imaging, serologic assessment for relevant infectious agents, and assessment of coagulation may also be beneficial.

Lens Opacification

Cataracts are a frequent cause of blindness in dogs, and the majority are inherited. Cataracts also can occur secondary to diabetes mellitus, retinal degeneration, hypocalcemia, trauma, nutritional deficiencies, electric shock, chronic uveitis, or lens luxation. Cataracts are uncommon in cats, but, when they occur, they are most commonly the result of uveitis or lens luxation. For a cataract to be the cause of blindness, the entire lens must be involved, and the cataract must be dense enough to prevent ophthalmoscopic evaluation of the ocular fundus. Cataracts alone do not interfere with the PLR. Therefore, if the PLR is abnormal, a retinal optic nerve, optic tract, CN III, or iridal lesion must also be present. Cataracts must be differentiated from nuclear (lenticular) sclerosis, which is a normal aging change. The cloudy appearance of the lens in nuclear sclerosis is caused by increased density of lens fibers, particularly within the nucleus, causing partial reflection of light. Unlike with cataracts, in patients with nuclear sclerosis the ocular fundus is visible by direct

or indirect ophthalmoscopy. Dilation of the pupil with tropicamide is essential for a complete lens examination and will facilitate differentiation between cataracts and nuclear sclerosis.

Vitreous Opacification

Blindness due to opacification of the vitreous can occur secondary to persistent hyperplastic primary vitreous (PHPV), which is a congenital abnormality caused by failed regression of the hyaloid vessel within the primary vitreous. This alone does not cause blindness, but PHPV usually is associated with persistence of embryologic remnants on the posterior lens capsule (persistent tunica vasculosa lentis) and/or vitreous hemorrhage. Leukocoria (“white pupil”) results from fibrovascular plaque formation immediately behind the posterior lens capsule. PHPV is inherited in the Doberman pinscher and Staffordshire bull terrier and occurs sporadically in other breeds.

Severe, diffuse hemorrhage or cellular infiltrate into the vitreous can result in blindness. The vitreous is avascular and contains very few cells; thus inflammation and hemorrhage result from disease in adjacent tissues (ciliary body, retina, choroid, or optic nerve). Vitreous hemorrhage can occur with iritis/pars planitis (intermediate uveitis) (see Chapter 262), systemic hypertension (see Chapter 159), retinal detachment (see Chapter 264), intraocular neoplasia (see Chapter 251), blood dyscrasias, and trauma. Vitreous centesis for cytology and bacterial and fungal culture are indicated in cases of inflammatory cell infiltrate if less invasive methods do not identify a cause.

RETINAL DISEASE

Chorioretinitis

The retina is in close approximation to the underlying choroid; thus retinitis frequently occurs secondary to inflammation of the choroid and therefore is referred to as chorioretinitis. Bilateral, diffuse, severe chorioretinitis causes blindness with a significantly reduced or absent PLR. Chorioretinitis is characterized by the presence of hazy, grayish-white, sometimes raised lesions within the ocular fundus. These will appear hyporeflective in the tapetal fundus. In severe cases there may be partial or complete retinal detachment. Potential causes include systemic mycoses (*Blastomyces dermatitidis*, *Cryptococcus neoformans*, *Histoplasma capsulatum*, *Coccidioides immitis*, *Aspergillus* sp., *Fusarium* sp.), *Ehrlichia canis*, *Rickettsia rickettsii*, canine distemper virus, *T. gondii*, feline infectious peritonitis virus, protothecosis, *Brucella canis*, bacterial septicemia, intraocular larval migrans, and neoplasia. There may be concurrent anterior uveitis. Diagnostic measures include those discussed for opacification of the aqueous humor. In addition, vitreous centesis for cytology and bacterial and fungal culture is indicated if detection of the etiologic agent is not possible by less invasive methods.

Retinal Detachment

Retinal detachment typically occurs between the retinal pigmented epithelium (RPE) and the photoreceptors (rods

and cones) and is therefore sometimes termed retinal separation. It must be bilateral and marked to cause blindness. The three mechanisms and common causes for retinal detachment are more fully discussed in Chapter 264. All patients with retinal detachment should undergo a complete physical examination and diagnostic testing as dictated by clinical findings.

Retinal Degeneration

Retinal degeneration is a common cause of blindness in dogs and cats. The typical ophthalmoscopic appearance of retinal degeneration is retinal vascular attenuation, diffuse tapetal hyperreflectivity, optic nerve pallor, and mottling of the nontapetal fundus. If the retina is not diffusely affected but has focal or multifocal hyperreflective tapetal or depigmented nontapetal lesions, there may be another cause for the blindness, and further evaluation is needed. Animals with blindness caused by retinal degeneration have a diminished or extinguished ERG.

Progressive retinal atrophy (PRA) refers to a group of inherited retinal diseases, including photoreceptor dysplasias and photoreceptor degenerations. PRA is much more common in dogs than in cats. In most forms of PRA the rods are affected earlier in the course of the disease than the cones, and the first clinical sign is decreased night vision (nyctalopia). The disease progresses to complete blindness in all light levels as the cones become affected. The age of onset and rate of progression of PRA vary by breed. The progression of vision loss can be very gradual such that the pet compensates extremely well and can be so gradual that owners may not detect vision loss until the animal is taken to a strange environment. As a result, these patients are occasionally presented for assessment of apparent acute blindness. Central progressive retinal atrophy (CPRA) is an uncommon disorder in dogs in the United States. CPRA is an RPE dystrophy with secondary retinal degeneration and thus appears as multifocal accumulations of pigment surrounded by hyperreflectivity. CPRA does not always lead to complete blindness.

Sudden acquired retinal degeneration (SARD) results in permanent blindness of acute onset and is seen only in adult dogs. In most cases the PLR is severely reduced or absent at the onset of blindness, but the retina and optic nerve appear ophthalmoscopically normal. SARD is confirmed by ERG, which is extinguished. The cause of SARD is unknown. Overweight female dogs of any breed, dachshunds, and miniature schnauzers are over-represented. Many dogs with SARD have a history of polyuria, polydipsia, and increased appetite (van der Woedt et al., 1991). These signs are temporary in 80% of dogs. Several weeks to months after the onset of blindness, clinical signs typical of retinal degeneration develop and are indistinguishable from other causes of end-stage retinal degeneration. Histologically the photoreceptors show severe degeneration without inflammatory changes immediately after the onset of blindness, with rods and cones equally affected.

Retinal degeneration in cats has been associated with oral and parenteral administration of enrofloxacin

(Wiebe et al., 2002). These cats have increased tapetal reflectivity, retinal vascular attenuation, and extinguished ERGs. Most cats are presented with acute blindness and pupil dilation (Gelatt et al., 2001). Onset or severity of disease may be dose related. Some cats regain partial vision, but in most the retinal degeneration persists or progresses. Other causes of retinal degeneration in cats include taurine deficiency in cats, vitamin E deficiency in dogs, and glaucoma in both species. End-stage glaucoma causes diffuse retinal degeneration, and there is concurrent optic nerve cupping and usually buphthalmos.

OPTIC NERVE DISEASE

Bilateral lesions of the optic nerves interfere with transmission of the image to the visual cortex and result in blindness and an absent PLR.

Optic Neuritis

Inflammation of the optic nerves (optic neuritis) can be caused by infectious agents (canine distemper virus, *T. gondii*, *B. dermatitidis*, *C. neoformans*, *H. capsulatum*, feline infectious peritonitis virus), granulomatous meningoencephalitis (GME), neoplasia, trauma, and idiopathic causes. In patients with optic neuritis, a swollen, indistinct optic disc with or without hemorrhage and exudation is seen funduscopically. The peripapillary retina may also be involved, with retinal edema, exudation, hemorrhage, and/or detachment all possible. Optic neuritis must be differentiated from papilledema in which the optic nerve head is swollen but without evidence of exudation, hemorrhage, blindness, or PLR deficits. Optic neuritis posterior to the globe (retrobulbar optic neuritis) results in blindness with a normal fundic examination. Patients with retrobulbar optic neuritis must be differentiated from those with SARD. This can be achieved simply and inexpensively by an ERG, which will be normal with optic nerve disease but extinguished with SARD. Patients with optic neuritis should undergo thorough physical and neurologic examinations. Diagnostic testing should then include assessment of a complete blood count, serum biochemistry panel, urinalysis, appropriate serologic testing, aspiration of lymph nodes if enlarged, thoracic and abdominal imaging if indicated, and MRI of the central nervous system with cerebrospinal fluid analysis.

Optic Nerve Atrophy

Optic nerve atrophy is apparent funduscopically because the optic nerve head is small, pale or, more chronically, darkly pigmented, depressed, and avascular. There is often associated peripapillary retinal degeneration evident as peripapillary tapetal hyper-reflectivity. Retinal vessels may or may not be severely affected, depending on the underlying cause. The PLR will be severely diminished or absent. Causes of optic nerve atrophy include previous optic neuritis, trauma, retrobulbar inflammation or compression, glaucoma, and end-stage retinal degeneration.

Congenital Optic Nerve Anomalies

Optic nerve hypoplasia is a congenital cause of blindness in which patients have a small (but otherwise normal) optic nerve head and an otherwise normal fundus. This should be differentiated from optic nerve atrophy in which the optic nerve head is not only small but altered and the peripapillary retina is degenerate. Optic nerve coloboma is a congenital notchlike defect of the optic nerve. Extensive colobomas can cause blindness and predispose to retinal detachment. Optic nerve colobomas can be a component of collie eye anomaly and are also frequently found in animals with microphthalmos and merle coat coloring.

INTRACRANIAL CAUSES OF BLINDNESS

The visual pathway has a long intracranial course. Lesions in the optic chiasm, optic tracts, and optic radiations result in failed transmission of the visual image. Lesions in the visual cortex result in failed interpretation (cognition) of the image. Lesions of the optic chiasm or bilateral optic tract lesions result in blindness with an abnormal PLR. Lesions posterior to the site where fibers responsible for the PLR branch from those responsible for vision (i.e., lesions of the lateral geniculate nucleus, optic radiation, or visual cortex) result in blindness with a normal PLR. Animals with blindness caused by intracranial disease typically have a normal fundic examination unless there is retrograde degeneration of the optic nerves. They will also have a normal ERG. Causes of intracranial blindness include neoplasia, GME, infectious agents (canine distemper virus, systemic mycoses, *T. gondii*, feline infec-

tious peritonitis virus), trauma, feline cerebral infarction, obstructive hydrocephalus, various storage diseases, and hypoxemia. Affected animals, especially those with chiasmal lesions, do not always show additional central nervous system signs. In a retrospective study the majority of dogs with blindness secondary to neoplasia of the optic chiasm did not have other CNS signs (Davidson et al., 1991).

Differential Diagnosis of Anisocoria

NANCY B. COTTRILL, *Woburn, Massachusetts*

Anisocoria, or different-size pupils, is abnormal. The clinician's role is to determine which pupil is abnormal and whether the underlying cause is ophthalmic or neurologic. This chapter is intended to provide a logical guide to address frequent owner concerns: What is wrong? What caused it? How is it treated? Will it get better? These goals are best achieved by first examining the eye with the normal pupil, the pupillary light reflexes (PLRs), and then the eye with the abnormal pupil. Identification of lesions will enable a short list of potential causes to be assessed. Once the cause is known, a prognosis can be given.

There are two types of anisocoria: static and dynamic. Static anisocoria refers to unequal pupils when both eyes are receiving equal illumination. In a patient with dynamic anisocoria, the difference in pupil size depends on one pupil being stimulated. Some degree of dynamic anisocoria is normal because of incomplete decussation of afferent (optic nerve) fibers at two locations: the optic chiasm and the pretectal nucleus. At the optic chiasm nerve fibers cross to the contralateral side, whereas at the pretectal nucleus nerve fibers cross back to the original (ipsilateral) stimulated side. Although pupils of both eyes react to light when it is directed at only one eye, the iris sphincter muscle of the directly stimulated eye receives more efferent impulses than the nonstimulated eye. Therefore it is normal for the pupil receiving direct stimulation to be smaller than the fellow (nonstimulated) pupil. This is termed physiologic dynamic anisocoria and does not indicate pathology.

In all patients in which anisocoria is diagnosed, a thorough medical history not restricted to ophthalmic or neurologic inquiries is essential. Standard questions should be posed regarding past medical history, current medications, current medical conditions, and physical signs. The owner should be asked about any trauma or an absence of the pet from its environment for a period of time, as well as prior treatment by either the owner or a previous veterinarian. Occasionally a veterinarian will use atropine in the examination room as a diagnostic tool instead of a more appropriate short-acting, dilating agent such as tropicamide. Alternatively owners may try home remedies, which can include medications used for a previous condition that may alter the pupil size. Because pupil dilation as a result of a single application of atropine may last 2 weeks in the uninflamed eye, this can confuse the diagnosis and confound diagnostic efforts.

A complete ophthalmic examination, including tonometry (measurement of intraocular pressure [IOP]) should

always be done. Other ophthalmic diagnostic tests such as application of fluorescein stain or measurement of a Schirmer's tear test should be done if indicated. Finally, a physical examination is done. Recording all examination findings is essential (Fig. 254-1). This activity is helpful in that it commits the examiner to a decision about the observations. It is also invaluable in compiling the information for review before making a decision regarding the etiology of the anisocoria.

ANATOMY OF THE PUPILLARY LIGHT REFLEX

Pupil size (and, in the cat, pupil shape) is determined by the balance between parasympathetic and sympathetic innervation of the iris. Although emotional and other nonneuroophthalmic factors can affect this, pupil size depends in large part on the amount of light illuminating the retina and the afferent and efferent pathways of the PLR. Therefore an understanding of the anatomy of the PLR is essential (Fig. 254-2).

The afferent arm of the PLR consists of the retina, optic nerve, optic chiasm, and optic tract. Nerve fibers originating in the medial retina decussate to the opposite optic tract, whereas fibers from the lateral retina remain in the ipsilateral tract. In the dog approximately 75% of the optic nerve fibers decussate to the contralateral optic tract. In the cat approximately 65% of the optic nerve fibers decussate. The optic tract includes both sensory visual fibers and pupillomotor fibers, which differ according to their destination. This fact is used to aid localization of lesions by noting the presence or absence of vision and PLR in each eye. The pupillomotor fibers progress to the pretectal nucleus, and from there the majority of these

Fig. 254-1 Grid to record visual status and pupillary light reflexes (PLRs). Entry variables include +, normal; —, absent; I, incomplete; M, minimal. The latter two variables are used to designate degrees of constriction in the PLRs (e.g., the "incomplete" designation may be used in cases of iris atrophy). The example in the chart depicts the responses of a lesion of the right retina or prechiasmatic optic nerve.

Fig. 254-2 Pathways for vision, the pupillary light reflex, and the sympathetic pathway affecting the eye. Numbers correspond to structures, as lesion sites, in Table 254-1. (Modified and redrawn from Oliver JE, Lorenz MD, Kornegay JN: Blindness, anisocoria, and abnormal eye movements. In *Handbook of veterinary neurology*, ed 3, Philadelphia, 1997, Saunders, p 275, with permission.)

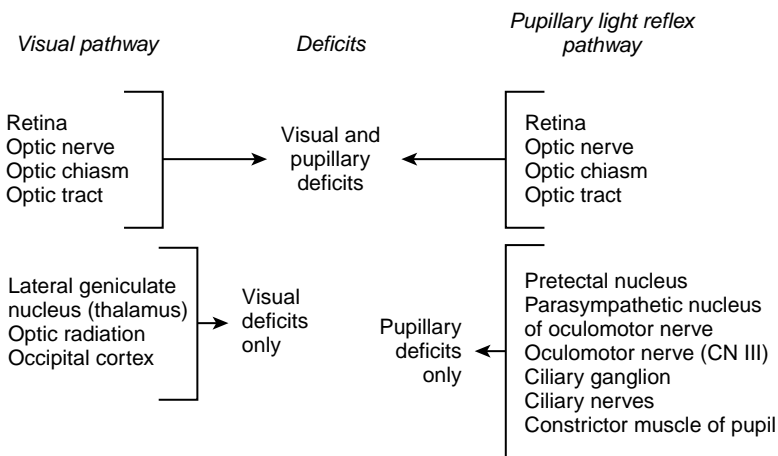

Fig. 254-3 Deficits from lesions of the visual and pupillary light reflex pathways. (From Oliver JE, Lorenz MD, Kornegay JN, editors: Blindness, anisocoria, and abnormal eye movements. In *Handbook of veterinary neurology*, ed 3, Philadelphia, 1997, Saunders, p 274, with permission.)

fibers decussate to the parasympathetic nucleus of the oculomotor nerve (once known as the Edinger-Westphal nucleus) on the contralateral side. This second decussation marks a return to the side of the originating impulse. By contrast, the visual fibers proceed sequentially to the lateral geniculate nucleus, the optic radiation, and the occipital cortex. Therefore lesions that cause anisocoria and affect both PLRs and vision can be localized to the

retina, optic nerve, optic chiasm, or optic tract (Fig. 254-3). By contrast, lesions affecting vision, but not PLRs, are located in the lateral geniculate nucleus, optic radiation, or occipital cortex.

The efferent arm of the PLR consists of parasympathetic fibers in the oculomotor nerve (CN III) that travel to the ciliary ganglion, ciliary nerves, and finally the iris sphincter muscle. There are distinct differences in composition

of the canine and feline postganglionic fibers (ciliary nerves). In the dog there are five to eight short ciliary nerves that have both sympathetic and parasympathetic efferent fibers and are considered "mixed." Therefore a lesion of the ciliary nerve in the dog results in a circular, midrange pupil because both parasympathetic and sympathetic fibers are lost. By contrast, the cat has only two short ciliary nerves that are solely parasympathetic. These nerves are named the nasal (medial) and malar (lateral) nerves. Therefore lesions involving these nerves cause more dramatic pupil dilation than in the dog because sympathetic function is still present and now unopposed. If only the medial or lateral branches are damaged, dyscoria (altered pupil shape) results in addition to anisocoria. For example, a lesion of the medial short ciliary nerve on the right eye will result in a D-shaped pupil, whereas a lesion of the lateral short ciliary nerve on the same eye will result in a reverse D-shaped pupil.

The sympathetic fibers largely innervate the iris dilator muscle. The three-neuron pathway that the sympathetic axons traverse is more complex. The central fibers originate in the hypothalamus and exit the brain with the tectotegmentospinal tract. The preganglionic cell bodies lie in spinal cord segments T1 to T3 and issue fibers with the spinal nerve ventral roots. These pass via the thoracic and cervical sympathetic trunk to terminate in the cranial cervical ganglion, caudal and medial to the tympanic bulla. Postganglionic fibers then exit the ganglion and pass via the cavernous sinus into the periorbital, nasociliary nerve, long ciliary nerve, ciliary body, and finally the iris dilator muscle.

THE OPHTHALMIC EXAMINATION

Observation of Facial Symmetry and Assessment of Cranial Nerves

A crucial part of the neuroophthalmic examination is observation of the carriage of the head and assessment of facial and ocular symmetry. It is quite easy to miss neurologic lesions by focusing on only the apparently affected eye in your assessment of anisocoria. For example, Horner's syndrome is most often recognized during the initial observation of facial symmetry. Cranial nerves other than the optic (CN II) and oculomotor (CN III) should also be assessed as part of the routine ophthalmic examination for a patient with anisocoria.

Visual Status

It is important to determine the visual status of each eye *before* checking the PLRs. The menace response is usually more notable during the initial part of the examination, before the pet has been subjected to bright lights shone in its eyes but after it is relatively calm on the table. A properly performed menace test, done without creating air currents or noise, is a helpful test of vision. However, observing an animal "track" cotton balls dropped in front of it while shielding one eye is perhaps a more reliable test of visual function. Brightly colored soft balls sold as kitten toys provide better contrast against the background of a white wall or clinician's white coat than a white cotton

ball. Maze tests and visual placing are additional tests of vision. Findings should be recorded (see Fig. 254-1).

Pupillary Light Reflexes

A direct PLR is elicited by directing a *bright* light source into the pupil. Ideally a focused, 3.5-volt halogen light source such as a Finoff transilluminator (Welch-Allyn, Skaneateles Falls, NY) is used. The Finoff transilluminator head can be attached to the battery handle used for a direct ophthalmoscope or otoscope. An excellent alternative to this is a halogen penlight (Welch-Allyn). The illumination from an ordinary penlight is too diffuse and often too dim to produce a reliable PLR. A weak light source decreases the amplitude and duration of pupil constriction and may induce a delay before pupil constriction begins. The light source should produce light of consistent brightness so that the examiner becomes familiar with the expected response in the examination room. Pupillary constriction on direct light stimulation is known as the direct PLR. Pupil constriction in the fellow eye is known as the consensual response and, as a result of incomplete decussation of fibers, is usually not quite as complete as the direct response (so-called *physiologic dynamic anisocoria*). If the PLR is incomplete, the light should be redirected to another part of the fundus since areas of the retina may have different light sensitivities, especially with focal or regional pathology of the afferent pathway; particularly the retina. It is easiest to see the direct and consensual PLRs by gently retracting both upper eyelids and directing the light into the eye being tested while an assistant holds the pet. The clinician can easily look at the consensual pupil while still directing the light into the other eye. Normal findings when performing PLRs include equal pupil size and shape in diffuse light, pupils that dilate almost maximally and equally in the dark, and brisk direct and consensual PLRs in both eyes with expected physiologic dynamic anisocoria. Direct and consensual PLRs should be assessed in ambient light first, with findings recorded as normal, absent, incomplete, or minimal (see Fig. 254-1). Committing to a response and some qualifying information about the response is valuable.

Swinging Flashlight Test

The swinging flashlight test is used to assess and compare the function of the retina and the prechiasmal optic nerve in one eye versus the other. A bright light is directed into one eye for a few seconds and then redirected into the fellow eye. The normal response is for the first pupil to fully constrict. Sometimes slight dilation occurs after full pupil constriction in a normal eye as a result of adaptation of the retina to the light stimulus. This is known as *pupillary escape*. As the light is swung to illuminate the second eye, the pupil should constrict a little further (or already be fully constricted as a result of the consensual PLR). An abnormal swinging flashlight test is noted when the pupil of the second eye dilates as the light is directed into it. This is known as a positive swinging flashlight test (or the Marcus Gunn sign) and is a hallmark of a lesion in the retina or prechiasmal optic nerve of the eye that dilates when illuminated.

Dark Adaptation Test and Retroillumination

Once these initial tests are completed, the lights should be turned off to allow the patient's and examiner's eyes to adapt to the darkness for approximately 2 minutes. The examiner should then stand back at arm's length from the patient with the light source set to emit bright illumination and centered between the *examiner's* eyes. This will permit the examiner to assess the tapetal reflex obtained simultaneously from both of the patient's eyes. In particular, the degree and symmetry of pupil dilation should be assessed since some causes of anisocoria are associated with more marked pupil asymmetry in dim than in bright ambient light. The examiner should repeat assessment of PLRs and the swinging flashlight test in the dark because differences are more marked after dark adaptation.

Completion of the Ophthalmic Examination

After vision testing, PLRs, retroillumination, and the swinging flashlight are assessed, a thorough ocular examination, including tonometry and assessment of aqueous flare, should be completed to identify or eliminate ophthalmic causes of anisocoria (see Chapter 248). This approach will allow the clinician to identify and confirm the presence of anisocoria, recognize the abnormal pupil, and begin consideration of causes under the broad mechanistic headings of "nonneurologic" (further divided into ophthalmic or pharmacologic causes) versus "neurologic" (further divided into afferent or efferent lesions).

NONNEUROLOGIC CAUSES OF ANISOCORIA

Ophthalmic Causes of Anisocoria

Ophthalmic causes of anisocoria can be divided into conditions that cause miosis (a constricted pupil) or those that cause mydriasis (a dilated pupil).

Conditions That Cause Miosis

Anterior uveitis (see Chapter 262) may cause miosis. Other signs that are variably present in patients with uveitis include corneal edema, "cloudiness" of the anterior chamber resulting from an increase in the protein content of the aqueous humor (aqueous flare), hyperemic conjunctival or episcleral vessels, and low IOP. PLRs may be sluggish or difficult to see because of extreme miosis. Severe or chronic uveitis may also cause posterior synechiae (adhesions between the iris and the anterior lens capsule) to form. Synechiae typically also cause dyscoria, and PLRs may be slow or absent, depending on the extent of the adhesions. Posterior synechiae may also form while the pupil is dilated and therefore need not always be associated with miosis. Corneal irritation, especially ulcers and lacerations, causes a reflex miosis mediated by the trigeminal nerve called the *axonal reflex*. These conditions are easily recognized by focal corneal edema, plus or minus a corneal stromal defect, and corneal retention of fluorescein dye. Therefore it is wise to apply fluorescein stain to all eyes with miosis as a presenting sign.

Conditions That Cause Mydriasis

Iris atrophy is a normal aging change resulting in an irregular or scallop-edged pupil, as well as transillumination defects in the iris caused by atrophy of the iris musculature. These defects are seen during retroillumination (i.e., by directing a light toward the fundus and observing light reflected from the tapetum through the pupil). In animals with iris atrophy, light can be seen through the body of the iris. Iris atrophy is more common in poodles and Siamese cats. Because the atrophy involves the iris muscles, PLRs typically are altered. Initial pupillary constriction may be normal or minimal; however, constriction is incomplete. Iris atrophy is usually bilateral, but not always symmetric, and such unevenness can produce anisocoria.

Iris hypoplasia is a congenital defect in iris stroma density visible as an area of irregular pigmentation. These areas typically appear dark because of increased visibility of the melanotic posterior pigmented epithelium of the iris, resulting from stromal thinning. The pupil margin may also be irregular and scalloped, and transillumination defects may be seen. Pupillary constriction characteristics are similar to those seen in patients with iris atrophy.

The pupil of glaucomatous eyes may be mydriatic. Other signs include episcleral congestion, generalized corneal edema, and IOP above normal. PLRs are often slow or absent. Visual deficits are also present if the IOP is markedly or chronically elevated. Iris tumors such as melanomas may cause mydriasis if they infiltrate the iridal musculature and impede its function. They may also produce mydriasis if they cause secondary glaucoma. Severe blunt ocular trauma can damage iridal sphincter fibers, with resultant iridoplegia.

Unilateral retinal disease can cause mydriasis, although the anisocoria tends to be relatively subtle (especially in dim ambient light) because decussation of afferent fibers causes stimulation of the iris of the affected eye via the contralateral retina. However, direct and consensual PLRs are typically slow or absent, and the swinging flashlight test should be positive. Visual deficits are usually present. In addition, visual deficits are usually present but may or may not be noted by owners since pets typically compensate well for unilateral vision loss. Fundic examination will reveal the cause of unilateral retinal causes of mydriasis. Perhaps the most common cause of unilateral retinal disease is retinal detachment, which has the ophthalmoscopic appearance of an undulating veil containing blood vessels coming toward the observer (see Chapter 264). Severe chorioretinitis that affects a large area in one eye or one eye more than the other can cause unilateral mydriasis. Areas of active chorioretinitis have a dull tapetal reflex, are often gray, and have indistinct edges. Unilateral optic neuritis and optic nerve neoplasia can also produce mydriasis and vision loss. Although there are multiple known causes of optic neuritis, many cases are idiopathic. The most common optic nerve tumor in the dog is a meningioma. Optic nerve causes of mydriasis usually produce ophthalmoscopically visible changes, but only the retrobulbar portion of the nerve may be affected, in which case the intraocular portion of the nerve may have a normal appearance. Orbital neoplasia, cellulitis, or retrobulbar abscess should also be considered in patients

with unilateral loss of vision, altered PLRs, and a positive swinging flashlight test. These patients should be assessed for evidence (sometimes subtle) of exophthalmos or decreased retropulsion.

Pharmacologic Causes of Anisocoria

Pharmacologic causes of anisocoria can be divided into drugs that produce miosis and those that produce mydriasis. Miosis is most often caused by administration of agents used for management of glaucoma. These include pilocarpine, demecarium bromide, or any of the new synthetic prostaglandins such as latanoprost. Mydriasis can be caused by administration of tropicamide or atropine, ocular contact with jimsonweed (*Datura stramonium*) or other toxic plants, or topical administration of collyria or ocular decongestants containing phenylephrine. The likelihood of exposure to pharmacologic agents that alter pupil size should be specifically elicited when the patient history is obtained.

NEUROLOGIC CAUSES OF ANISOCORIA

Afferent Versus Efferent Pupillary Defects

Neurologic causes of anisocoria should be neuroanatomically localized as afferent or efferent. Although a complete ophthalmic examination and history of exposure to pharmacologic agents are essential, monitoring the change in anisocoria during dark adaptation will greatly assist with localization.

Afferent Lesion Characteristics

Anisocoria caused by an afferent arm lesion is abolished (or sometimes reduced) as both pupils dilate in the dark.

This is because the stimulus producing the anisocoria (light causing constriction of the normal pupil but inadequate constriction of the abnormal pupil) is eliminated. Thus anisocoria caused by afferent lesions is less prominent in dim ambient light and more prominent in bright light. In addition, afferent lesions cause abnormal PLRs in *both* the abnormal and the normal pupil (Table 254-1; see Fig. 254-2). If the pupils remain unequal or do not dilate completely in the dark, the lesion must be in the sympathetic efferent arm or be ophthalmic or pharmacologic in origin.

Efferent Lesion Characteristics

Signs of lesions involving the efferent arm of the PLR produce some dramatically different signs, depending on:

- Whether they affect the parasympathetic or sympathetic neurons of the efferent arm.
- Whether they affect the central (for the sympathetic supply) or preganglionic or postganglionic (for both parasympathetic and sympathetic supplies) neurons.
- Whether the patient is feline or canine.
- The intensity of the ambient light in which the examination is conducted.

These differences are discussed more fully in the following paragraphs. However, efferent lesions of any type or site do not cause visual deficits in either species (see Table 254-1 and Fig. 254-2).

Afferent Lesions

Unilateral Retinal or Prechiasmal Optic Nerve Lesions

Patients with unilateral retinal or prechiasmal lesions have mydriasis (usually subtle) and a slow or absent

Table 254-1

Signs of Lesions in the Visual Pathways*

†Unilateral lesions of these structures are rare.

‡Possibly loss of sight in left visual field with partial sparing of right visual field.

direct PLR on the affected side but a normal consensual PLR from the unaffected to the affected eye. They also have visual deficits on the affected side and a pathognomonic positive swinging flashlight test. The last feature is pathognomonic for lesions at these sites. The fundus should be examined for presence of retinal or optic nerve head pathology. If the fundic examination is normal, an electroretinogram (ERG) can be done to localize the lesion further. If the ERG is normal (i.e., the retina is functioning) and the optic nerve head is funduscopically normal, the retrobulbar (but prechiasmal) optic nerve is affected.

Unilateral Optic Tract Lesions

Patients with unilateral optic tract lesions have a mydriatic pupil (usually subtle) in the eye contralateral to the affected optic tract, regardless of which eye is receiving the light stimulus, visual deficits, and a negative swinging flashlight test. Unlike prechiasmal lesions, the pupil *contralateral* to the lesion is affected in postchiasmal lesions because of decussation. Because the majority (75% in dogs, 65% in cats) of CN II fibers in each optic tract decussate from the contralateral optic nerve, the pretectal nucleus on the affected side no longer receives that input, no impulses progress to decussate a second time to the contralateral parasympathetic nucleus of CN III, and stimulation of the oculomotor nerve on the contralateral side does not ensue. The eye contralateral to the optic tract lesion also will have a partial visual deficit because the majority of the optic tract is composed of fibers from the medial retina of the contralateral eye.

Optic Chiasm Lesions

Chiasm lesions rarely cause anisocoria; rather they usually cause bilateral mydriatic pupils, absent PLRs, and vision loss.

Efferent Lesions

Parasympathetic Efferent Lesions

In dogs the preganglionic efferent nerves are purely parasympathetic, but the postganglionic nerves are mixed. In cats both nerves are purely parasympathetic over their whole course. Therefore lesion site and species affected cause notable differences in the pupillary signs seen.

Lesions of the nucleus of CN III, the preganglionic fibers, or the ganglion itself produce similar signs in dogs and cats. There will be diminished or absent PLRs on the affected side to both direct and indirect light, normal direct and consensual PLRs on the unaffected side, normal vision, and equally and maximally dilated pupils in the dark.

In cats lesions of the ganglion or postganglionic nerves cause signs identical to those of preganglionic lesions because only parasympathetic fibers are affected. However, pupil shape also will differ if only one of the two postganglionic short ciliary nerves is affected (as discussed earlier in "Anatomy of the PLR"). By contrast, ganglionic or postganglionic lesions in the dog cause anisocoria after dark adaptation, with the smaller pupil being ipsilateral

to the lesion because the mixed nature of these nerves in the dog means that lesions affect the ability of the pupil to constrict and dilate.

Pupil changes induced by dysfunction of the autonomic components of CN III are termed internal ophthalmoplegia. This differentiates them from external ophthalmoplegia, which occurs following damage to the oculomotor fibers that also run in CN III and which is manifest as ptosis (drooping of the upper lid) and lateral strabismus. Dogs and cats can experience internal ophthalmoplegia without concurrent external ophthalmoplegia because the parasympathetic fibers are superficial and medial to the oculomotor fibers of CN III and therefore are more susceptible to injury than the oculomotor fibers. Internal ophthalmoplegia may be the result of trauma from proptosis; retrobulbar disease such as abscess, cellulitis, hemorrhage, or orbital or optic nerve neoplasm; or midbrain lesions.

Pharmacologic Localization of Parasympathetic Lesions

Pharmacologic testing may be used to confirm presence of a lesion in the efferent arm of the PLR, rule out pharmacologic blockade and iridal disease, and localize the lesion as preganglionic or postganglionic. A lesion in the ganglion or postganglionic fibers causes *denervation hypersensitivity* to what would normally be an ineffective concentration of a topically administered parasympathomimetic drug. The first agent used in localizing a lesion in the parasympathetic efferent pathway is an indirect-acting parasympathomimetic such as 0.5% physostigmine. The desired response is miosis. The pupil of an eye with a central or preganglionic lesion will constrict sooner than one with normal parasympathetic innervation. The pupil of an eye with a lesion in the ciliary ganglion or postganglionic fibers will not constrict. Application of dilute pilocarpine (< 0.2%) is perhaps the most useful test for the general practitioner. Denervation hypersensitivity will cause the affected pupil to constrict sooner and more completely and to maintain the constriction longer in response to this low concentration of a direct-acting parasympathomimetic than the pupil in the normal eye. Application of a more concentrated direct-acting parasympathomimetic agent such as 2% pilocarpine can be used to simply confirm the presence of an efferent arm lesion (and to rule out mechanical obstruction such as synechia, iris atrophy, or pharmacologic mydriasis). However, this will not define the lesion location.

Sympathetic Efferent Lesions

The loss of sympathetic tone to the eye is commonly known as Horner's syndrome (HS). Signs of HS are always ipsilateral to the lesion and include miosis, ptosis, protrusion of the third eyelid, and enophthalmos. Miosis may remain after the other signs have disappeared. About 50% of canine cases and 42% of feline cases of HS are idiopathic (Kern, Aromando, and Erb, 1989). However, the patient should be investigated for commonly identified causes of HS in small animals such as trauma to the head, neck, or chest; brachial plexus root avulsion;

intracranial, mediastinal, or intrathoracic neoplasia; otitis media/interna; and injury to the ear during cleaning. Dogs that are tethered outside and repeatedly lunge at the end of the tether are at risk for neck trauma and HS. Golden retrievers and collies are suggested to be predisposed. Most idiopathic cases of HS will resolve in 4 to 16 weeks.

Pharmacologic Localization of Sympathetic Efferent Lesions

As with parasympathetic lesions, pharmacologic testing may be used to confirm presence of a sympathetic lesion in the efferent arm of the PLR, rule out pharmacologic blockade and iridal disease, and further localize the lesion. The same principles of denervation hypersensitivity apply (i.e., lesions of the ganglion or postganglionic neuron cause hypersensitivity); however, in this case mydriasis is the desired response. Ideally the first step is to instill an indirect-acting sympathomimetic such as 1% hydroxyamphetamine into both eyes; however, this drug is difficult to obtain commercially. When it is applied topically, the affected pupil will dilate if the lesion is central or preganglionic, whereas no or little dilation will occur if the lesion is postganglionic. An easier way to confirm the diagnosis of HS is to instill a dilute direct-acting sympathomimetic such as 1% phenylephrine into each eye. Both eyes should be reassessed every 10 minutes until pupil dilation has occurred in the affected eye or until 40 minutes have passed. The denervated (hypersensitive) pupil reacts by dilating before or in the absence of pupillary dilation in the unaffected eye. The other signs of HS may also diminish during this pharmacologic challenge. Some authors suggest that, if mydriasis occurs before 20 minutes, the lesion is postganglionic; and, if it occurs between 20 and 45 minutes, it is likely preganglionic. The phenylephrine test alone does not allow discrimination between a preganglionic and central lesion.

Spastic Pupil Syndrome

This syndrome occurs only in cats and is characterized by static anisocoria (at the time of examination), failure to dilate after dark adaptation, normal vision, and no ocular abnormalities. The curious feature of this syndrome is that the degree of anisocoria and the relative size of the pupils can change from day to day (i.e., the anisocoria can be caused by a relative miosis or mydriasis, and this can change). There may even be intervals when the pupils are normal. Most cats with this syndrome are determined to have positive feline leukemia virus tests.

Differential Diagnosis of the Red Eye

DIANE V.H. HENDRIX, *Knoxville, Tennessee*

Red eye is perhaps the most common clinical sign observed by pet owners when ocular disease is present. However, knowledge that a patient has a red eye does not give any specific indication as to type or severity of disease or prognosis. This requires the gathering of a complete history, performance of a thorough ophthalmic examination, and diagnostic testing. First, one must localize the source of the redness noted by the owner. Ocular redness may be focal or generalized. It may involve the adnexa, exterior of the globe, or the interior of the globe. Redness of the adnexa or exterior of the globe may involve the conjunctiva, the third eyelid, the episcleral region, or the cornea. Redness from within the globe may be caused by hemorrhage in the anterior chamber or vitreous, retinal detachment, or neovascularization of the iris. Despite the diversity of causes, ocular redness may be the only obvious sign present in blinding diseases such as glaucoma and anterior uveitis and thus should always be thoroughly investigated. The purpose of this chapter is to introduce the causes of and diagnostic approach for a red eye. The reader is referred to other chapters devoted to specific ocular diseases for information regarding ocular diagnoses introduced in this chapter.

LOCALIZING THE SOURCE OF THE REDNESS

When an animal has a red eye, it is imperative that the precise anatomic location of the redness be determined since this will aid in determining the etiology (Fig. 255-1). The redness may be focal or generalized, involve surface or intraocular structures, and be superficial or deep. The most important aspect of localizing ocular redness is differentiating conjunctival vessels from episcleral vessels; this will permit differentiation of irritating surface eye disease such as conjunctivitis from potentially blinding intraocular disease such as glaucoma or uveitis. If an eye with a blinding disease such as glaucoma or anterior uveitis were treated as if only conjunctivitis were present, vision loss would be likely. Ocular redness associated with conjunctivitis involves the capillaries of the conjunctiva. These superficial blood vessels blanch more rapidly with topical application of dilute (1%) phenylephrine or epinephrine than deeper episcleral vessels. Conjunctival vessels are also more mobile in comparison to episcleral vessels. Vascular mobility can be determined by moving the bulbar conjunctiva by sliding the eyelid over the globe using gentle digital pressure; or a moistened cotton-tipped applicator can be used to lightly slide the

conjunctiva over the sclera after topical anesthetic has been instilled. If the engorged vessels are easily moved with either of these techniques, they are conjunctival vessels.

Surface redness associated with intraocular disease tends to involve the episcleral vessels. The episcleral vessels are larger and less mobile than conjunctival vessels. In addition, these vessels do not blanch quickly following topical application of dilute epinephrine or phenylephrine. They may radiate caudally from the limbus as is seen frequently with glaucoma, or they may primarily involve the perilimbal region as is seen commonly with anterior uveitis.

The eye may also appear red if chronic corneal disease has led to corneal vascularization or corneal granulation tissue. In addition, blood in the anterior chamber (hyphema) may make the cornea appear red and completely obscure the iris and pupil. Vitreous hemorrhage can also cause the eye to appear red; however, this must be distinguished from the normal red fundic reflection in dogs and cats with a subalbinotic fundus. Finally, a retinal detachment may cause reddening of the eye because of retinal blood vessels visible against the posterior aspect of the lens.

Once the source of redness has been localized, a complete ocular examination should be performed to diagnose the current disease process, establish a prognosis, and determine appropriate treatment. Pupillary light reflexes; menace response; Schirmer's tear test; intraocular pressure; fluorescein staining of the cornea; examination for aqueous flare; and complete examination of the eyelids, cornea, iris, lens, vitreous, and fundus should be done (see Chapter 248).

Focal Redness

Focal redness is usually caused by subconjunctival hemorrhage or a mass. Trauma resulting from a dog fight or excess pressure applied around the neck by a collar is the most common cause of subconjunctival hemorrhage. Although the hemorrhage may appear severe, no treatment is necessary provided that the remainder of the examination is normal. If there is no historical trauma, the possibility of a systemic bleeding disorder caused by vasculitis or coagulopathy should be investigated. Prolapse of the gland of the third eyelid ("cherry eye") is the most common cause of a red mass on the eye. The prolapsed gland should be replaced by either burying the gland using the pocket technique or tacking the gland to the orbital rim. Neoplasia of the conjunctiva is rare but

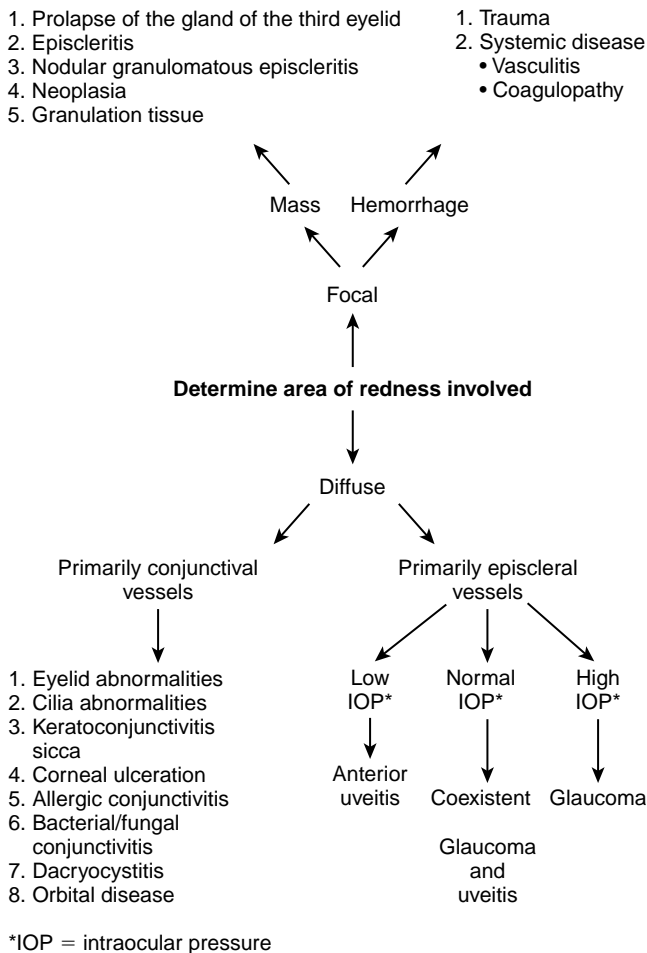

Fig. 255-1 Algorithm for determining the cause of a red eye in dogs or cats.

does occur; biopsy of any questionable mass is indicated (see Chapter 251). Episcleritis and nodular granulomatous episcleritis are inflammatory diseases that produce focal red-to-tan masses, most commonly at the lateral limbus (see Chapter 259).

Generalized Redness

Conjunctival Redness (Conjunctival Hyperemia)

Localization of redness to the conjunctiva is consistent with a clinical diagnosis of conjunctivitis. However, there are many causes of conjunctivitis in dogs and cats (see Section XII on Evolve). More important, dogs and cats with potentially blinding intraocular disease such as anterior uveitis and glaucoma often have conjunctival hyperemia, usually in conjunction with sometimes subtle episcleral injection. Therefore a diagnosis of conjunctival hyperemia or episcleral injection is not mutually exclusive, and the presence of conjunctival hyperemia should stimulate very thorough investigation to prove or disprove the presence of episcleral hyperemia. In the case of episcleral injection with conjunctival hyperemia, the intraocular disease is the primary threat, and with its treatment the conjunctival hyperemia will resolve. Complete ophthalmic examination of a dog or cat with

isolated conjunctivitis should reveal negative retention of fluorescein stain, normal intraocular pressures, and normal pupillary light responses.

Conjunctivitis. Although conjunctivitis literally means inflammation of the conjunctiva and conjunctival hyperemia refers to dilation or congestion of the conjunctival capillaries, the terms are often used interchangeably. Unfortunately “conjunctivitis” usually creates thoughts of mild, nonthreatening vision disease. However, there are many causes of conjunctivitis, some of which (such as corneal ulceration or keratoconjunctivitis sicca [KCS]) can be blinding. Although there is some overlap, causes of feline and canine conjunctivitis tend to differ. Generally conjunctivitis in cats should be considered infectious; therefore treatment with steroids is often contraindicated (see Chapter 257); whereas primary conjunctival pathogens of the dog are very uncommon (see Section XII on Evolve).

In dogs KCS is a common cause of conjunctivitis, and it is the most common primary cause of bacterial conjunctivitis in dogs. Clinical signs of KCS include a mucoid-to-mucopurulent discharge; conjunctivitis; and a dull cornea that may be ulcerated, pigmented, or vascularized. Because of the high incidence of this disease in dogs, a Schirmer’s tear test should be done on all dogs with conjunctivitis. A result below 10mm/min of wetting is diagnostic for KCS. A result of 10 to 14mm/minute of wetting is suggestive of KCS, and treatment should be based on clinical signs or the results of a retest at a later date. Treatment for KCS includes replacing the tears with an artificial tear ointment, resolving secondary bacterial infections with a broad-spectrum antibiotic, and increasing tear production with topical cyclosporine or tacrolimus (see Chapter 249 and Section XII on Evolve).

Mechanical irritation is a common cause of conjunctival hyperemia in the dog. Distichia, ectopic cilia, trichiasis, entropion, and ectropion are all common etiologies. Conjunctival hyperemia, epiphora, or a mucoid discharge and corneal disease may be seen. A complete ocular examination is warranted because occasionally the most apparent abnormality such as distichia, trichiasis, or ectropion may not be the only cause of the conjunctivitis. When it has been determined that an eyelid/eyelash abnormality is causing the ocular signs, the appropriate surgical therapy should be undertaken.

Allergic conjunctivitis associated with atopy is often seasonal. Clinical signs are usually restricted to conjunctival hyperemia and epiphora. Control of the atopy in conjunction with a topical antihistamine often resolves clinical signs. Follicular conjunctivitis also is thought to be caused by local antigen exposure and usually affects young large-breed dogs. Ocular examination reveals an abundance of lymphoid follicle formation, conjunctival hyperemia, and epiphora. The follicles most commonly occur on the bulbar side of the third eyelid but may also occur on the palpebral side or another conjunctival surface. Cytologic examination of scrapings of the follicles reveals numerous lymphocytes. Topical application of a corticosteroid will frequently bring relief. Allergic and follicular conjunctivitis caused by antigen exposure occurs much less commonly in cats than dogs; infections such as those due to *Chlamydomydia felis* are more common causes of conjunctivitis in cats.

Canine distemper virus frequently causes conjunctivitis with epiphora or a mucoid-to-purulent discharge. KCS, corneal ulceration, chorioretinitis, and optic neuritis may also be present in association with systemic signs. Cytologic evaluations of conjunctival scrapings from the gland of the third eyelid may reveal cytoplasmic inclusion bodies, but they are rarely seen. Direct or indirect immunofluorescent antibody testing of the conjunctival scrapings may also be diagnostic. Fluorescein stain interferes with immunofluorescent antibody testing; therefore samples should be acquired before using fluorescein stain. Treatment with topical antibiotics to prevent secondary bacterial infections and treatment with tear replacement ointments may be indicated.

Primary bacterial conjunctivitis is very rare in the dog. *Staphylococcus* sp. is usually the offending bacteria. Dogs with bacterial conjunctivitis have a purulent ocular discharge with or without swollen eyelid margins. Cytology, culture, and nasolacrimal duct flush (to rule out dacryocystitis) should be done. Ophthalmic antibiotics are usually indicated. Systemic antibiotics are necessary if the eyelids are involved or if dacryocystitis is present. The choice of antibiotic should be based on culture and sensitivity results. If a complete and rapid response does not occur with treatment, the patient should be reevaluated.

Conjunctivitis in cats is almost exclusively infectious in nature. The most common agents are feline herpesvirus I (FHV-1; also known as feline rhinotracheitis virus) and *C. felis*. Primary infection with FHV-1 is manifest by sneezing and ocular and nasal discharge in young cats. Their conjunctivitis is characterized by conjunctival hyperemia and some chemosis. Serous ocular discharge later becomes mucoid to mucopurulent. Most cases spontaneously resolve in 10 to 14 days; however, most cats become latently infected. A percentage of adult cats then will show unilateral ocular disease without upper respiratory signs. In these adults the disease is more likely to be chronic or recurrent. Fluorescent antibody techniques, virus isolation, and polymerase chain reaction may aid in diagnosis in acute infections (see Chapter 258 and Section XII on Evolve).

C. felis (formerly *Chlamydia psittaci*) is a common cause of conjunctivitis in cats. The disease is unilateral initially and becomes bilateral. Clinically chemosis and a serous ocular discharge are seen. Cytology may reveal intracytoplasmic inclusion bodies, or fluorescent antibody testing may be of benefit. Topically applied oxytetracycline or erythromycin are effective; however, systemically administered doxycycline or azithromycin may be preferred (see Chapter 257). *Mycoplasma* spp. have been associated with conjunctivitis in cats; however, they also can frequently be cultured from normal cats. Clinical signs include unilateral or bilateral epiphora, papillary hypertrophy of the conjunctiva, chemosis, and pseudomembrane formation. Treatment with ophthalmic oxytetracycline administered four times daily is generally effective.

Occasionally a dog or cat is seen following exposure to a chemical irritant. In these cases corneal ulceration is likely, and fluorescein staining is essential. The cornea and conjunctiva (including the fornices) should be flushed copiously with sterile saline. Treatment with a

broad-spectrum antibiotic ointment for lubrication and to prevent bacterial infection of any ulcerated surfaces is recommended.

Clinical signs of corneal ulceration include blepharospasm; conjunctival hyperemia; photophobia; an uneven corneal surface; vascularization of the cornea; and sometimes aqueous flare and miosis. Fluorescein stain retention in the region of ulceration is diagnostic. The primary cause of the corneal ulcer must always be determined by doing a complete ophthalmic examination. Most corneal ulcers will heal rapidly when the cause is removed and when treated with a topical broad-spectrum antibiotic and a parasympatholytic drug such as ophthalmic atropine. If the ulcer is deep or rapidly progressing, culture and placement of a conjunctival graft may be required (see Section XII on Evolve).

Orbital disease causes secondary conjunctival hyperemia caused by inflammation, exposure, and decreased venous return; therefore reddened eyes should be retro-pulsed. If exophthalmos is present or the affected globe is difficult to retropulse, orbital disease should be suspected (see Section XII on Evolve).

Episcleral Redness

Anterior uveitis. The episcleral redness associated with anterior uveitis is often localized to a somewhat circumferential region behind the limbus and is referred to as *ciliary flush*. Clinical signs of anterior uveitis include miosis, resistance to pupillary dilation with mydriatic agents, anterior or posterior synechia, a darkened iris, and decreased intraocular pressure. The presence of circulating blood components in the anterior chamber (aqueous flare, hypopyon, keratic precipitates, hyphema) is pathognomonic for anterior uveitis. To detect aqueous flare, the smallest white light spot on the direct ophthalmoscope is focused on the cornea. If aqueous flare is present, the light will be scattered, and a continuous beam of light will extend from the cornea to the lens. Low levels of aqueous flare are best detected in a completely dark room. A slightly miotic pupil is more noticeable in a darkened room as well (see Chapter 248).

Anterior uveitis has a multitude of etiologies (see Chapter 262); patients warrant a thorough general physical examination and often systemic disease testing. The goals of treatment of anterior uveitis are to decrease inflammation and prevent sequelae such as synechia, cataract formation, iris bombé, secondary glaucoma, and blindness. Pending an etiologic diagnosis, the eye should be treated topically with parasympatholytic drugs such as atropine (1% ophthalmic solution or ointment) or tropicamide (1% ophthalmic solution). These drugs dilate the pupil, thereby decreasing the iris-to-lens contact and preventing or decreasing the severity of posterior synechia formation, and decrease pain by paralyzing the ciliary body muscle. Topically applied corticosteroids that penetrate an intact corneal epithelium such as prednisolone acetate or dexamethasone are used to decrease inflammation. Hydrocortisone will not penetrate into the anterior chamber and should not be used. Corticosteroids are contraindicated when a corneal ulcer is present. Topical ophthalmic nonsteroidal antiinflammatory drugs may also be used; however, they are not as efficacious as steroids alone.

However, topical ophthalmic nonsteroidal antiinflammatory drugs may be used in the presence of noninfected corneal ulcers; they do not affect diabetic management as corticosteroids do and can have synergistic effects with topical corticosteroids in refractory inflammation.

Hyphema. Hyphema refers to the presence of free blood in the anterior chamber. Often these patients also have episcleral injection. There are many causes of hyphema, and observation of this sign should trigger further examination and diagnostic investigation. A single episode of hemorrhage such as that caused by trauma generally resolves quickly. Recurrent bleeding such as that seen secondary to a retinal detachment, an intraocular tumor, chronic uveitis, vasculitis, systemic hypertension, or coagulopathy may lead to secondary glaucoma or synechia formation. If evaluation of the retina is not possible because of the hyphema, ocular ultrasonography may delineate a retinal detachment. Pending diagnosis, topical prednisolone acetate should be initiated, provided the cornea is not ulcerated. Intraocular pressure should be evaluated periodically and treated appropriately if secondary glaucoma develops.

Glaucoma. Glaucoma is frequently overlooked as a cause of a red eye. One reason for this is that early glaucoma

(intraocular pressure <35 mm Hg) often causes only conjunctival hyperemia with or without epiphora and with no other clinical signs. These dogs are frequently treated for “conjunctivitis” when they actually have episcleral injection. Later, when pressures are extremely elevated, many other clinical signs such as pain, corneal edema, mydriasis, blindness, optic nerve cupping, retinal degeneration, buphthalmos, and lens subluxation are also often present. Another frequent reason glaucoma is overlooked is failure to assess intraocular pressure. Tonometry should be performed on all dogs and cats that have a red eye unless a descemetocoele is present or the globe is ruptured. Breed predisposition should heighten suspicion of glaucoma (see Chapter 263).

CHAPTER 256

Diseases of the Eyelids and Periocular Skin

CATHERINE A. OUTERBRIDGE, *Davis, California*

STEVEN R. HOLLINGSWORTH, *Davis, California*

The eyelids and periocular skin can be affected by a large variety of dermatologic diseases. Inflammation of the eyelids is called *blepharitis*, and many affected animals also have dermatitis elsewhere. In addition, the eyelid margin is a mucocutaneous junction, and the skin diseases that target mucocutaneous junctions often involve the eyelids. This chapter considers some of the more commonly seen medical conditions that can affect the eyelids or periocular skin of dogs and cats.

INFECTIOUS BLEPHARITIS

Bacterial Blepharitis

The most common reason for bacterial blepharitis relates to infections caused by *Staphylococcus* spp. Bacterial infec-

tion of eyelids is often secondary to another condition that alters the cutaneous microenvironment and favors bacterial colonization. Hypersensitivity or allergic reactions (e.g., atopic dermatitis or cutaneous adverse food reactions), can cause the animal to self-traumatize the area. Facial fold pyoderma occurs in certain breeds, particularly those that are brachycephalic. If the folds are close to the eyelids, moisture accumulation and bacterial colonization may occur within the skinfolds and extend to the eyelids. Mucocutaneous pyoderma can also develop secondary to a “drainage board” effect at the medial canthi in dogs with chronic epiphora.

Clinical signs of bacterial blepharitis include erythema, swelling, depigmentation, alopecia, and variable degrees of ulceration and crusting. There may be pruritus, particularly if bacterial blepharitis is secondary to underlying

allergic disease. There may also be concurrent mucopurulent ocular discharge. Treatment should include appropriate systemic and topical antibiotics and identification of any underlying predisposing skin or ophthalmic disease. In some dogs, surgical removal of facial skin folds may be beneficial or curative.

Bacterial infection of the various glands within the eyelid is termed *hordeolum*. Such infections, usually *Staphylococcus* spp. are thought to originate from the ocular surface flora. Infection of the glands of Zeis or Moll is termed *external hordeolum* or *stye*. Similar involvement of the meibomian glands is referred to as *internal hordeolum*. Both conditions are more frequently seen in young dogs and may represent immune deficiency during the juvenile period. The clinical presentation of both conditions is similar, consisting of swollen, inflamed, and painful eyelid margins. The course is often self-limiting but may be shortened with application of hot compresses along with administration of broad-spectrum topical ophthalmic and systemic antibiotics.

A chalazion results when meibomian secretions thicken, obstruct the duct, and cause the buildup of secretory material in the gland. This eventually leads to glandular rupture and lipogranuloma formation. Clinically chalazia present as firm, noninflamed nodules within the eyelid. When viewed through the palpebral conjunctiva, they appear as aggregates of yellow material. Treatment involves incision of the overlying palpebral conjunctiva and curettage of the granulomatous material. Postoperative treatment is topical application of an ophthalmic antibiotic-steroid ointment for 7 to 14 days.

Fungal Blepharitis

The most common fungal organisms identified in the dog or cat with dermatophytosis are *Microsporum canis*, *Microsporum gypseum*, and *Trichophyton mentagrophytes*. These fungal organisms are adapted to colonize hair and cornified layers of the skin, where they digest keratin protein. Most animals must come in contact with a minimum infective dose of dermatophyte spores for infection to become established. This dose varies related to the individual animal's overall health and immunologic status.

Dermatophytosis in dogs often results in localized lesions, most commonly affecting the face, feet, or tail. Dogs are often presented with the classical circular alopecia with scale, crust, and follicular papules. A kerion is a localized inflammatory lesion secondary to a dermatophyte infection and presents clinically as a well-circumscribed nodular lesion of furunculosis, often located on the face or distal extremity. Dermatophyte lesions in cats are more pleomorphic. Classic lesions include one or more areas of partial alopecia, with scaling and crusting most commonly noted on the head or forelimbs. Dermatophytosis can also result in lesions that resemble miliary dermatitis.

The clinical appearance of skin lesions is unreliable as the sole criterion for diagnosis of dermatophytosis, and additional tests are required. A Wood's lamp examination can be helpful in some cases but is unreliable as only 50% of *M. canis* infections fluoresce, and most other dermatophyte species do not react at all. Definitive diagnosis

of dermatophytosis is grounded in culture and identification of the organism. Culture samples can be obtained from hairs plucked from suspicious lesions based on clinical appearance or from fluorescence positive areas as observed with a Wood's lamp.

Topical therapy has long been advocated for the treatment of dermatophytosis. However, numerous studies have shown that topical therapies alone are less effective than systemic therapy. Lime sulfur and enilconazole are the two most effective antifungal topical therapies. Systemic antifungal therapy has been demonstrated to decrease both the duration and severity of dermatophytosis. Itraconazole (10mg/kg) is now the preferred recommended systemic therapy for treatment of dermatophytosis. Ketoconazole (10mg/kg), fluconazole, griseofulvin, and terbinafine are other antifungal agents with activity against dermatophytes.

Malassezia pachydermatis is a normal commensal inhabitant of the skin and external ear canal in dogs and cats. The organism may cause dermatitis as a result of inflammatory or hypersensitivity reactions to yeast antigens by the host. Most dogs with *Malassezia* dermatitis have concurrent dermatoses. Dogs with allergic dermatitis often have increased numbers of *Malassezia* colonizing their skin, and, when treated appropriately with antifungal therapies, both the overall appearance of the skin and the degree of pruritus will improve. About 40% of allergic dogs with *Malassezia* dermatitis also have concurrent superficial pyoderma. The diagnosis of generalized *Malassezia* infection in a cat is strongly linked to concurrent serious systemic disease: diabetes mellitus, positive retroviral status, and internal neoplasia. *Malassezia* dermatitis is diagnosed on the basis of cytologic documentation of increased numbers of the yeast organism. Topical treatment (miconazole, ketoconazole) may be effective, but in chronic or generalized cases systemic therapy with 5mg/kg of ketoconazole, fluconazole, or itraconazole daily may be necessary. Griseofulvin has no activity against *Malassezia*.

Parasitic Blepharitis

Parasitic blepharitis is most commonly caused by infestation with *Demodex* mites. *Demodex canis* is the most commonly identified *demodex* mite in the dog, but there is also a long-bodied mite, *D. injai*, and an unnamed short-bodied mite. The most common form of demodicosis is localized disease, which is most commonly seen in animals younger than 10 months of age. Clinically dogs are presented with focal areas of alopecia, erythema, and scaling, often involving the face and feet. Generalized demodicosis covers larger areas of the body and is more common in certain breeds such as the Staffordshire terrier, Chinese shar-pei, English bulldog, Boston terrier, boxer, and pug. Clinically there can be marked areas of alopecia and erythema. Complete alopecia of the eyelids and periorcular regions develop in some dogs. A cause for generalized demodicosis in adult dogs, such as immunosuppression resulting from underlying disease or a history of chronic corticosteroid use, is found in about 50% of cases. Concurrent bacterial folliculitis or deep pyoderma is almost always present in generalized demodicosis and

should be treated appropriately. Feline generalized demodicosis with *D. cati* is also often associated with underlying systemic disease. *D. gatoi* is a short-bodied mite that lives in the stratum corneum and can be a cause of contagious pruritus in cats.

Diagnosis of demodicosis is based on identification of the mite on deep skin scrapings or hair pluckings. Multiple life stages and eggs may also be identified. For localized demodicosis no treatment is needed; it will resolve spontaneously as the dog matures. Dogs with generalized disease should be spayed because the disease may be exacerbated by estrus, and it is a heritable trait. Generalized demodicosis can be treated with total body dips with Amitraz, which is the only licensed therapy for canine demodicosis. "Off-label" systemic therapy with ivermectin (0.4 to 0.6 mg/kg daily) or milbemycin (1 to 2 mg/kg daily) is effective for generalized demodicosis (ensure the patient is heartworm microfilaria negative). Ivermectin should never be used in breeds known or suspected to be sensitive to this drug. Dogs can be tested for carriage of the multidrug resistance gene (MDR-1) that conveys sensitivity to ivermectin toxicity. Regardless of which treatment is used, therapy should be continued for 1 month past the second consecutive monthly skin scraping in which mites are not detected.

Feline Herpetic Ulcerative Dermatitis

Feline herpesvirus-1 (FHV-1) is a common pathogen of domestic cats worldwide that is associated with acute and chronic rhinitis, numerous ocular diseases, stomatitis, and ulcerative facial and nasal dermatitis. Cats with herpetic dermatitis develop ulcerative skin lesions most commonly on the dorsal muzzle and nasal planum, but lesions can involve the medial canthus and periocular regions. Pruritus is variable. Cats may not have any other concurrent signs of FHV-1 infection.

Diagnosis is based on compatible histopathology from skin biopsies of representative lesions. The presence of intranuclear viral inclusions in cells obtained from the face of a cat with marked ulcerative dermatitis is diagnostic. Eosinophilic inflammation also may be evident in affected tissues. If viral inclusions are not found, polymerase chain reaction (PCR) for FHV-1 can be performed on formalin fixed tissue samples taken from skin biopsies. In one study a negative PCR result held a 100% negative predictive value.

Treatments for herpetic ulcerative dermatitis can include subcutaneous interferon- α at 1 million units/m² or systemic antiviral drugs such as famciclovir. Secondary bacterial dermatitis may develop; thus appropriate systemic antibiotics may be warranted initially.

ALLERGIC BLEPHARITIS

Causes of allergic eyelid disease include atopy and food allergy. Immune-mediated skin disorders can also affect the eyelids (see later in this chapter).

Atopic Dermatitis

Atopic dermatitis is a pruritic, inflammatory, allergic skin disease in genetically predisposed animals. The prevalence of canine atopic dermatitis has been estimated to be

up to 10%. Breeds predisposed to atopic dermatitis tend to vary geographically. In general, boxers, retrievers, and terrier breeds are overrepresented for this disease. Most dogs show clinical signs of atopic dermatitis between 1 and 3 years of age, and initially the clinical signs are often seasonal. The most common clinical manifestation is pruritus, particularly involving the face, including ears, feet, axillae, and ventrum. Dogs self-traumatize pruritic areas, resulting in lesions of alopecia, erythema, and excoriations. Lichenification and hyperpigmentation can develop in chronic lesions.

Atopic dermatitis is diagnosed on the basis of appropriate signalment, history, and clinical findings and the exclusion of all other causes of pruritic skin disease. Treatment is aimed at decreasing the individual dog's pruritic threshold. This often involves the elimination of any secondary bacterial and *Malassezia* infections; identification of any other concurrent allergic skin diseases; and judicious and prudent use of antihistamines, corticosteroids (topical and systemic), allergen-specific immunotherapy, or cyclosporine in various combinations. Details are discussed more fully throughout Section 5 of this volume.

Cutaneous Adverse Food Reaction (Food Allergy)

A cutaneous adverse food reaction (food allergy) is presumed to be a hypersensitivity reaction to ingested allergens. Food allergy occurs in both dogs and cats, and clinically affected animals demonstrate nonseasonal pruritus that results in lesions caused by self-trauma that include erosions, ulcerations, excoriations with varying degrees of alopecia, lichenification, and hyperpigmentation or erythema. The face, ears, extremities (feet), and ventrum are most commonly affected. Otitis externa is also a common feature of canine food allergy.

Food allergy is diagnosed by compatible history and clinical signs and confirmation of improvement on a strict elimination diet trial using a novel protein diet and relapse on challenge provocation with the original diet (see Section XII on Evolve).

METABOLIC/NUTRITIONAL BLEPHARITIS

Zinc-Responsive Dermatitis

Zinc-responsive dermatosis is a metabolic skin disease that often affects the periocular region in affected dogs. Arctic breeds such as Siberian huskies and Alaskan malamutes are most commonly affected, but it can be observed in other breeds. Two syndromes of zinc-responsive dermatosis are recognized in dogs. Syndrome I has been identified in Siberian huskies, Alaskan malamutes, and occasionally other breeds. These dogs are speculated to have a genetic defect in the intestinal absorption or metabolism of zinc. Dogs with this disease manifest signs even when fed well-balanced diets. Syndrome II occurs in rapidly growing puppies that are often being fed a poor-quality dog food or are being oversupplemented with calcium. These juvenile dogs are thought to have a relative zinc deficiency caused by a combination of low zinc intake and the zinc-binding

effects of calcium or phytate in the diet. Dogs affected by syndrome I typically present with scaling, crusting, and alopecia of the mucocutaneous junctions, elbows, and footpad margins. Dogs affected by syndrome II are young large-breed dogs that have generalized crusting, plaques with extensive crusting, and fissuring of the footpads. Diagnosis is based on appropriate signalment and dietary history, typical cutaneous lesions, and histopathology of skin biopsies that reveal marked follicular and epidermal parakeratotic hyperkeratosis.

Many dogs with syndrome II respond simply to feeding a better-quality diet. Other dogs with syndrome II and all dogs with syndrome I require zinc supplementation with 2 to 3 mg/kg of elemental zinc in the form of zinc sulfate, zinc gluconate, or zinc methionine. To date, differences in clinical response have not appeared to depend on which zinc salt is used. Affected female dogs often respond to lower dosages of zinc after being spayed. Clinical signs typically improve within 4 to 6 weeks. Response to zinc supplementation is dramatic in syndrome II zinc deficiency, and therapy is not needed once the dog has reached maturity. Dogs with syndrome I zinc deficiency require ongoing therapy.

Superficial Necrolytic Dermatitis

Superficial necrolytic dermatitis (SND) (or hepatocutaneous disease) is an uncommon skin disease. However, it is being reported with increasing frequency in older dogs, and there have been recent rare reports in cats. Males appear overrepresented in several studies, and the mean age of affected dogs was 10 years. Some dogs with SND have elevated serum glucagon levels, and in a minority of dogs with SND a glucagon-secreting pancreatic tumor has been identified. However, most dogs with SND have a characteristic metabolic hepatopathy. It is unclear at this time what metabolic pathways may be linking liver or pancreatic disease with these skin lesions.

Cutaneous lesions include erythema, crusting, exudation, ulceration, and alopecia of the face (often periorcular and perioral regions), genitalia, and pressure points on the trunk and limbs. There is also a marked hyperkeratosis, fissuring, and ulceration of the footpads that is very suggestive clinically. Secondary cutaneous infection with bacteria, yeast, or dermatophytes can also be present; particularly involving the feet. The skin disease may precede any systemic signs. Common clinical signs include development of characteristic skin lesions, lameness secondary to footpad lesions, inappetence, weight loss, polydipsia, and polyuria. The polydipsia and polyuria typically are associated with concurrent diabetes mellitus, which is present in up to 30% of dogs with SND.

Histopathologic findings of a marked parakeratotic epidermis with striking intercellular and intracellular edema in the upper epidermis and hyperplastic basal cells create the so-called “red, white, and blue” lesion that is considered diagnostic for this disease. Elevation of liver enzymes and hypoalbuminemia are common clinicopathologic changes. Glucosuria and hyperglycemia may be documented if diabetes mellitus is present. Abdominal ultrasound often reveals a very characteristic honeycombed pattern to the liver, consisting of variable-size hypoechoic

regions surrounded by hyperechoic borders. Grossly livers of affected dogs appear cirrhotic. However, a vacuolar hepatopathy with minimal fibrosis (inconsistent with cirrhosis) is histologically evident in most affected dogs. Many dogs with SND have dramatic reductions in the plasma amino acid concentrations. The hypoaminoacidemia most likely reflects increased hepatic catabolism of amino acids.

Prognosis is poor, with mean survival times of 3 months. However, some dogs have been managed for over a year. Palliative therapy with intravenous and oral amino acid supplementation, often with concurrent oral supplementation with zinc and essential fatty acids, has improved cutaneous lesions in some dogs. Secondary skin infections should also be treated. If present, diabetes mellitus requires appropriate management. Removal of a glucagonoma has been reported to result in resolution of lesions in one dog.

IMMUNE-MEDIATED BLEPHARITIS

Pemphigus Foliaceus

Pemphigus foliaceus (PF) is often considered the most common of the autoimmune skin diseases in the dog. The Akita, bearded collie, chow-chow, Newfoundland, Schipperke, and Doberman pinscher are predisposed to this disease. The English springer spaniel, Chinese shar-pei, and collie also appear to be at increased risk of developing PF. Mean age of affected animals is between 4 and 5 years; but dogs of any age, breed, or sex can develop PF. Three forms are suggested to occur in the dog; these are differentiated by historical information. Spontaneous PF is most common. Drug-induced PF is clinically indistinguishable from spontaneous PF. Therefore obtaining a drug history (particularly any previous antibiotic administration) is critical for all patients with PF. Some cases of PF may occur in patients with a history of chronic, ongoing inflammatory skin disease such as allergic dermatitis. This is important to consider in chronic dermatologic patients that develop atypical or more severe lesions than previous episodes.

Clinically PF is a pustular and crusting disease that often involves the face and head. Most common affected sites include dorsal muzzle, nasal planum, pinnae, periorcular skin, and paw pads. Nasal planum and haired dorsal muzzle typically are affected concurrently. Truncal lesions are often diffuse, and paw pad lesions vary considerably in their severity. Intraoral lesions are never a feature of PF. If present, pustules are often large but may quickly progress to adherent crusts. Lesions may occur in “waves” so that the disease may seem to wax and wane in severity. If present, pustules should be biopsied. Older crusted lesions that are no longer tightly adherent often are not diagnostic. Histologically subcorneal pustules containing acantholytic cells often span multiple hair follicles. Pustules with acantholysis can also involve follicular epidermis. Neutrophils predominate within the pustules.

In humans Desmoglein 1 (Dsg 1) is the primary targeted autoantigen in PF. Dsg 1 is an integral protein component of the desmosomes in the superficial layers of the epidermis. Desmosomes are responsible for intercellular cohesion, and, when these structures are damaged, acantholysis results. Until recently Dsg 1 was also believed to

be the primary autoantigen in PF in the dog. However, recent evidence suggests that other proteins composing the desmosome may be more common autoantigens targeted in canine PF.

PF should be considered when a dog presents with acquired pustular/crusting disease that is generalized or strongly facial or fails to respond to antibiotics. Differential diagnoses include superficial bacterial folliculitis, superficial pustular dermatophytosis, demodicosis, sebaceous adenitis, and epitheliotropic T cell lymphoma.

Prognosis for PF is generally fair. However, a recent retrospective study found that 50% of dogs diagnosed with PF were euthanized within 1 year of diagnosis; usually as a result of complications from immunosuppressive drug therapy. Dogs that were initially concurrently treated with staphicidal antibiotics tended to have a better prognosis. Prednisone or prednisolone monotherapy rarely maintains remission of PF as dosages are decreased. Therefore concurrent use of azathioprine or chlorambucil is recommended to spare the adverse effects of corticosteroids. A small percentage of dogs with PF can be managed with combination therapy with tetracycline and niacinamide. Focally affected areas sometimes can respond to topical immunosuppressive therapy.

Pemphigus Erythematosus

Pemphigus erythematosus (PE) is a very rare, crusting autoimmune skin disease. It is considered to be a more benign form of PF or a crossover between PF and systemic lupus erythematosus (SLE). The collie and the German shepherd may be breeds at increased risk. Lesions have been proven to be aggravated by light exposure.

Lesions are confined to the face and include crusting, alopecia, and erosions of the dorsal muzzle, pinnae, and periocular areas. The nasal planum is often involved with depigmentation, crusting, and erosions. Biopsies of intact pustules or adherent crusts are most diagnostic. Histologically subcorneal pustules with acantholytic cells (as seen in PF) are present with concurrent interface dermatitis with basal cell damage (as seen in lupus erythematosus). A definitive diagnosis requires immunologic confirmation via immunohistochemistry or immunofluorescence and a positive antinuclear antibody (ANA) test. Differential considerations include facially predominant PF, discoid lupus erythematosus (DLE), superficial pustular dermatophytosis, epitheliotropic T cell lymphoma, uveodermatologic (or Vogt-Koyanagi-Harada-like) syndrome, and SLE.

Systemic Lupus Erythematosus

Skin lesions may be present in fewer than 20% of cases of canine SLE. The cutaneous lesions are pleomorphic, with erythema, scaling, crusting, depigmentation, and ulceration that often involve face, ears, and distal extremities. Panniculitis and oral ulcerations have also been seen. SLE is a progressive disease, and evidence of immunologic involvement in multiple organ systems may not always be evident on the initial presentation.

Biopsies should be taken of intact epidermis. The classic histologic lesion of SLE is an interface dermatitis.

Immunohistochemistry reveals a band of positive fluorescence at the basement membrane zone. Polyarthritis, protein-losing nephropathy, neutropenia, thrombocytopenia, hemolytic anemia, and polymyositis all have been reported in association with SLE. A thorough systemic evaluation, including a complete blood cell count, serum biochemistry, urinalysis, urine protein-to-creatinine ratio, antinuclear antibody test (ANA), arthrocentesis, and cytologic evaluation of joint fluid is warranted in patients suspected of having SLE. Most patients with SLE have an elevated ANA, although this may not always be present. Immunosuppressive therapy is required.

Erythema Multiforme

Erythema multiforme (EM) is an uncommon, acute eruption of the skin and mucous membranes characterized by erythematous macules and papules, crusting, vesicles, ulcers, and urticarial plaques. Annular target lesions with central pallor may be present. Lesions are seen on the trunk, groin, axillae, ears, mucocutaneous junctions, and oral mucosa. Histologically individual cell necrosis of keratinocytes—with or without satellitosis—is the most common lesion in EM. EM likely reflects a multifactorial etiology in which drugs, infection, or neoplasia may be triggers of the skin lesions. In about 50% of canine cases an underlying trigger cannot be found. Drug-induced EM minor is often self-limiting once medications are stopped. Severe generalized mucocutaneous EM (EM major) often requires aggressive supportive care, removal of underlying triggers, and immuno-suppressive therapy.

IATROGENIC BLEPHARITIS

Adverse reaction to topical medications can result in marked eyelid inflammation, with resultant alopecia, erythema, crusting, erosions, and ulcerations. Neomycin is one of the most common topical medications to cause an adverse reaction. If ophthalmic medications cause an adverse reaction, lesions will likely involve the eyelid and possibly the medial canthus owing to a drainage effect. Diagnosis is based on compatible history of use of topical medication. If adverse topical reaction is suspected, all topical medication should be discontinued, and the affected area cleaned. If the inflammatory reaction is severe, systemic or topical corticosteroids may be required.

Self-trauma can result in marked inflammation, with lesions of alopecia, excoriations, and crusting. Affected animals need to be evaluated for secondary infections with bacteria or yeast, evidence of demodicosis, and the possibility of allergic dermatitis.

PIGMENTARY CHANGES INVOLVING THE EYELID

A number of diseases can result in hyperpigmentation or a loss of pigmentation of the cutaneous regions around the eyes.

Lentigo simplex of orange cats is a cosmetic dermatologic condition in which intraepidermal melanocyte proliferation occurs, resulting in hypermelanosis in a macular pattern. The lentigines are well-demarcated black macules

that occur most commonly along lip margins, nasal planum, and eyelid margins and increase in size and number. Diagnosis is based on compatible signalment and clinical presentation. No treatment is necessary.

Vitiligo is an acquired immunologic loss of melanocytes that results in patchy or macular hypopigmentation. Belgian Tervurens, rottweilers, and German shepherds are predisposed. Lesions of leukotrichia or leukoderma are typically seen on the nasal planum, lip margins, eyelid margins, dorsal muzzle, and paw pads. Diagnosis is based on compatible history and clinical lesions and histopathology. The disease may wax and wane and, because it is asymptomatic except for esthetic concerns, no therapy is warranted.

Uveodermatologic (or Vogt-Koyanagi-Harada-like) Syndrome

Uveodermatologic syndrome is an uncommon canine immunologic disease that results in granulomatous uveitis and symmetric depigmenting facial skin lesions. Akitas and arctic breeds are at increased risk for the development of uveodermatologic syndrome. Characteristic lesions of leukoderma and leukotrichia with variable erythema and crusting involve the nasal planum, lips, eyelids, and periocular regions.

Diagnosis is based on appropriate signalment, clinical signs, and characteristic histopathology of representative skin biopsies. Treatment requires systemic immunosuppression for therapy of the dermatitis and uveitis, which is often blinding because of retinal detachment or development of secondary glaucoma (see Chapter 262).

Epitheliotropic T cell lymphoma can result in depigmentation often involving mucocutaneous junctions such as the eyelids, nasal planum, and lip margins. It is discussed more fully later in the chapter.

NEOPLASTIC BLEPHARITIS

Meibomian Gland Adenoma

Meibomian gland adenoma is the most common adnexal neoplasm in dogs. These neoplasms are almost always benign, with malignancy being manifested only by rapid local growth, not by adjacent tissue invasion or distant metastasis. Although studies have not demonstrated a consistent breed predisposition, occurrence of this neoplasm is definitely associated with advancing age. The clinical signs consist of a nodular swelling within the eyelid and a papilloma-like growth extending through the duct opening at the eyelid margin. The neoplasm itself typically does not cause discomfort or significant inflammation but is problematic because of its proximity to the cornea. Signalment and clinical appearance allow for a tentative diagnosis that is subsequently confirmed with histopathology. Numerous effective treatment options are available, including wedge resection, laser ablation, or debulking and curettage with adjunctive cryotherapy.

Papillomas

Papillomas also are a relatively common eyelid neoplasm in dogs. Unlike meibomian adenomas, these are found

in young dogs. They are almost always self-limiting, and treatment is rarely indicated.

Squamous Cell Carcinoma

Squamous cell carcinoma (SCC) is the most common adnexal neoplasm in cats, although adnexal tumors are far less frequently observed than in dogs. Metastasis is a potential problem but usually occurs only late in the disease course. However, the neoplasm can be locally aggressive, and spread to regional lymph nodes is not uncommon. White-haired coats and actinic radiation are thought to be involved in the pathogenesis. Common clinical presentation is an ulcerative, crusty lesion along the margin of the lower eyelid. Surgical excision, radiation therapy, and cryotherapy all are effective. SCC or actinic dermatitis occurs in areas that are poorly pigmented and in animals with a history of solar exposure. Lesions are initially erythematous, with crusting that progresses to ulceration. Eyelid margins, nasal planum, dorsal muzzle, and pinnal extremities in white animals are the most common sites for lesions.

Lymphosarcoma

Both dogs and cats can have adnexal manifestation of *lymphoma*, which is characterized by diffuse chemosis and conjunctival hyperemia. Although lymphoma is usually accompanied by other ocular or nonocular signs, conjunctival biopsy can be helpful in providing a diagnosis when it is affected.

Epitheliotropic T cell lymphoma often results in pigment loss with erythema around mucocutaneous junctions such as the eyelid, lip, or philtrum. Other cutaneous lesions can include exfoliative erythroderma and nodular or ulcerative lesions. Diagnosis is made by histopathology sometimes with immunohistochemistry of representative skin biopsies. Systemic therapy with lomustine or retinoids appears to offer the best clinical response.

Mast Cell Tumors

Mast cell tumors also can affect both dogs and cats. These tumors usually appear as noninflamed nodules within or under the eyelid skin. They are usually benign in this location. Diagnosis is by fine-needle aspirate or biopsy. Treatment options include surgical excision and radiation therapy.

MISCELLANEOUS EYELID DISEASES

Juvenile Sterile Granulomatous Dermatitis and Lymphadenitis/Juvenile Cellulitis (“Puppy Strangles”)

This disease is seen almost exclusively in puppies. Dachshunds, golden retrievers, and Labrador retrievers seem to be predisposed. The initial clinical sign is acute onset of facial swelling affecting the eyelids, muzzle, and lips. This develops into lesions of erythematous papules, pustules, and nodules that rupture and form crusts

or fistulae. These lesions most commonly develop in the periocular regions, dorsal muzzle, and pinnae. Concurrent lymphadenopathy, lethargy, and fever are common. The disease is very characteristic in its clinical appearance, but *generalized demodicosis* and *primary bacterial infection* need to be ruled out with appropriate cytologic sampling. Histopathology of representative skin biopsies may be necessary to make a definitive diagnosis in early lesions. Affected puppies respond quickly to immunosuppressive doses of glucocorticoids, suggesting some underlying immune dysfunction.

Canine Reactive Histiocytosis

Canine reactive histiocytosis occurs as either a cutaneous or systemic form. Both forms target the skin and subcutaneous tissue; but in the systemic form lymph nodes, conjunctiva, sclera, nasal planum/nares, lungs, spleen, and bone marrow also can be involved. Often skin lesions are multiple, nonpruritic, cutaneous papules, plaques, or nodules that may be alopecic and can ulcerate. Lesions occur most commonly on the head, neck, dorsum, perineum, extremities, and scrotum.

Diagnosis is based on histopathology from skin biopsies of representative lesions. Treatment involves immunosuppressive drugs. Cyclosporine and leflunomide have generated the best clinical response in this disease.

Entropion

Entropion is defined as a rolling in of the eyelid margin that subsequently leads to contact of the eyelid skin with the ocular surface. Entropion is often classified as breed related, spastic, or cicatricial. Breed-related entropion is usually apparent as soon as eyelid margins “open” at about 10 to 14 days postpartum and most frequently seen in dogs. Different breeds often exhibit entropion in different eyelid locations. Midsize-to-large breeds most often have entropion of the lateral aspect of the lower eyelid. Small and toy breeds demonstrate entropion of the medial aspect of the lower lid. All aspects of both eyelid margins are usually involved in shar-peis. Clinical signs of entropion are blepharospasm, epiphora, and wetting of the eyelid skin in the affected areas and corneal ulceration, vascularization, and/or melanosis if the eyelid skin is in contact with the cornea. The appropriate correction is determined by the age of the patient and the eyelid area involved. Dogs under 1 year of age should not have permanent surgical repairs. Such adolescent patients are managed with topical lubricants or eyelid-tacking procedures until they are old enough for surgery. The most commonly used surgical repair of entropion is the Hotz-Celsus technique.

Spastic entropion occurs as a result of ocular surface pain and may or may not be associated with other types of entropion. Because of the potential of spastic entropion, all patients diagnosed with entropion should be further evaluated after the instillation of a topical anesthetic such as proparacaine.

Cicatricial entropion is secondary to eyelid laceration or other injury. In some instances the fibrotic tissue

responsible can be identified and excised. Alternatively, a “V-to-Y” surgical technique may prove beneficial.

Ectropion

Ectropion results when the lower eyelid loses contact with the ocular surface. Most instances are breed related in dogs, although this condition can be caused by old age and weakening of the orbicularis oculi muscle. Breeds with “droopy” eyes such as cocker spaniels, bloodhounds, Saint Bernards, and mastiffs are commonly affected. Frequently the only sign associated with ectropion is a mild mucoid discharge and conjunctivitis. If the condition is severe enough, exposure keratitis can result, with accompanying blepharospasm, corneal ulceration, vascularization, and melanosis.

Usually no treatment is indicated for ectropion. In mild cases topical lubricants or antibiotic-steroid combination preparations may be used symptomatically. If corneal lesions are present, a laterally placed wedge resection may be used to “tighten” the lower eyelid.

Distichiasis

The meibomian glands are modified hair follicles. In *distichiasis* some glands fail to differentiate, and the resultant cilium emerges from the ductal opening. This condition occurs in both dogs and cats and is common in some canine breeds, including American cocker spaniels and golden retrievers. Although distichiasis usually does not produce clinical signs, it can lead to blepharospasm, epiphora, and rarely corneal ulceration. Because distichiasis is usually innocuous, manual epilation is advised to confirm that distichia cilia are actually responsible for the patient's clinical signs before more aggressive therapeutic measures are undertaken. When necessary, distichiasis is treated by epilation with cryotherapy.

A variant of distichiasis is *ectopic cilia*. With this condition the undifferentiated meibomian gland gives rise to a cilium that protrudes through the palpebral conjunctiva. Such cilia usually are located approximately centrally in the upper eyelid and may not emerge from the conjunctiva until about 1 year of age. Once they come in contact with the ocular surface, they cause an acute onset of marked blepharospasm and epiphora. They may also cause vertically linear, superficial corneal ulceration. Treatment of ectopic cilia is surgical excision of the palpebral conjunctiva containing the offending cilia and cryotherapy.

Trichiasis

Trichiasis occurs when facial hairs from normal locations come in contact with the ocular surface. It is most commonly seen in small, brachycephalic dog breeds. These hairs often “wick” tears onto the face in the medial canthal region but rarely lead to significant irritation. If they are deemed to be problematic, they can be removed with cryotherapy.

Feline Chlamydiosis

JANE E. SYKES, *Davis, California*

Although *Chlamydophila felis* (formerly *Chlamydia psittaci*) was once known as the organism responsible for feline pneumonitis, it is now recognized largely as a conjunctival pathogen. In fact, *C. felis* and feline herpesvirus type 1 (FHV-1) are believed to be responsible for the vast majority of feline cases of conjunctivitis. Despite this prevalence, recent information suggests that chlamydial organisms other than *C. felis* may cause ocular disease in cats and that *C. felis* can be found at sites other than the eye. Perhaps this explains why topical ocular therapy alone is often unsuccessful in satisfactorily resolving clinical signs of chlamydiosis in feline patients. This chapter presents a review of feline chlamydiosis, emphasizing diagnosis of ocular signs and therapy. For diagnosis and treatment of FHV-1, see Chapter 258 and Section XII on Evolve.

Chlamydiae are obligate intracellular bacteria. The chlamydial developmental cycle involves an alternation between the predominantly extracellular, infectious elementary body (EB), measuring 0.3 μm in diameter, and the intracellular, metabolically active reticulate body (RB), measuring 0.5 to 1.5 μm in diameter. For most chlamydiae the RB divide within an intracellular vacuole called an *inclusion*. The RBs then reorganize into EBs, which are subsequently released from the host cell and may enter a new, uninfected host cell, where they reorganize into RBs. Chlamydial EBs survive only a few days at room temperature. They are easily inactivated with lipid solvents and detergents.

Until recently only one chlamydial organism had been identified in cats, *C. felis* (previously *C. psittaci* var. *felis*). Other chlamydial organisms recently implicated as possible causes of feline conjunctivitis have been shown to belong to the family Parachlamydiaceae, a group of organisms (endocytobionts) that reside within free-living amoebae (Von Bomhard et al., 2003). *Neochlamydia hartmannellae* is found within *Hartmannella vermiformis*, the most common amoeba found within potable water supplies in the United States and a suspected cause of amoebic keratitis in man. The importance of *N. hartmannellae* as a causative agent of feline conjunctivitis and possibly keratitis has not been elucidated.

PATHOGENESIS

C. felis appears to have a predilection for conjunctival epithelial cells. Natural transmission presumably occurs by close contact with other infected cats and their aerosols and via fomites. It is unclear whether venereal transmission occurs in cats. The incubation period is approximately 3 to 5 days.

Infections caused by chlamydiae tend to follow a chronic, insidious course, often progressing through asymptomatic stages; this may be because of chlamydial persistence within tissues. Human chlamydial infections lasting over a decade have been reported, and *C. felis* has been isolated from the conjunctiva in cats for up to 215 days after experimental infection (Wills, 1986). Most cats cease conjunctival shedding at approximately 60 days after infection, although cats may continue to harbor persistent chlamydiae (O'Dair et al., 1994). Prolonged rectal and vaginal excretion by cats with chlamydial conjunctivitis has been documented, suggesting that the intestinal and reproductive tracts may be sites of persistent infection (Wills, 1986). *C. felis* has also been found in the lung, spleen, liver, kidney, and peritoneum of cats, although the significance of infection at these sites is not clear. Hematogenous dissemination has been documented (TerWee et al., 1998) and may explain the presence of this agent at such sites. Regardless, the systemic nature of chlamydial explains why topical ophthalmic application of appropriate antibiotics does not eliminate infection.

Chlamydial disease may be complicated by coinfection with other microorganisms such as feline calicivirus (FCV) or FHV-1. Cats with concurrent FCV infection often have signs such as oral ulceration in addition to conjunctivitis. The concurrent presence of FHV-1 should be considered in cats with keratitis that test positive for *C. felis*. Both *Mycoplasma* spp. and *Bordetella bronchiseptica* can also complicate *C. felis* infections. Coinfections with feline immunodeficiency virus prolong the duration of conjunctivitis and chlamydial shedding (O'Dair et al., 1994). Other bacteria can also act as secondary invaders and worsen disease.

CLINICAL SIGNS

Although previously referred to as the "feline pneumonitis agent," *C. felis* is primarily a conjunctival pathogen capable of causing acute or chronic conjunctivitis with blepharospasm, chemosis, conjunctival hyperemia, and serous-to-mucopurulent ocular discharge. Transient fever, inappetence, and weight loss may occur shortly after infection, although most cats remain well and continue to eat. Clinical signs improve after a few weeks, but mild conjunctivitis often persists for months. Nasal discharge and sneezing may occur in some cats; however, presence of these signs without concurrent ocular involvement is highly unlikely to be associated with *C. felis* infection. The conjunctivitis is typically associated with a neutrophilic infiltrate. *C. felis* has been isolated from cats with

neonatal conjunctivitis, although most kittens appear to be protected by maternally derived antibody.

C. felis infection alone is not a confirmed cause of keratitis, in contrast to chlamydial infections of other species. Non-*C. felis* chlamydiae such as *N. hartmannellae* do not appear to be more likely than *C. felis* to cause keratitis, despite the association between keratitis and infection with the amoeba *H. vermiformis* in humans. The ability of chlamydiae to cause corneal disease may also depend on strain and/or host factors.

EPIDEMIOLOGY

The prevalence of *C. felis* in cats with upper respiratory tract disease URTD as determined using culture has ranged from 23% to 31%. Studies using polymerase chain reaction (PCR) on conjunctival swabs from cats with ocular signs or signs of URTD have resulted in prevalence estimates of 12% to 20%. In the study in which novel feline chlamydiae were detected, an additional 88 of 226 cats (39%) had deoxyribonucleic acid evidence of non-*C. felis* chlamydial infection (Von Bomhard et al., 2003).

Cats less than 1 year of age are most likely to be infected with *C. felis*. Cats older than 5 years of age are least likely to be infected with *C. felis*. In contrast, the prevalence of infection with non-*C. felis* chlamydiae was higher (54%) in cats older than 10 years old than in cats less than 1 year old (30%). Chlamydial infection does not appear to have a strong breed or sex predilection.

The prevalence of *C. felis* in clinically normal cats is low; in studies using PCR less than 5% of cats are without clinical signs. Persistent chlamydial shedding after resolution of clinical signs may explain positive results in some normal cats. In contrast, the prevalence of non-*C. felis* chlamydial infection in asymptomatic cats was higher (6 of 30) (20%) (Von Bomhard et al., 2003). This was not significantly different from that in cats with ocular disease; thus further investigation of the importance of these organisms as causes of conjunctivitis in cats is required.

ZOONOTIC POTENTIAL

There is weak evidence that *C. felis* infection may be associated with conjunctivitis in humans. The most convincing evidence was documented recently, when a chlamydial organism was isolated from a human immunodeficiency virus-positive man with chronic conjunctivitis who had recently acquired a stray queen and its kittens (Hartley et al., 2001). Molecular evidence of *C. felis* infection has been detected in a small percentage of humans with respiratory tract disease (Corsaro et al., 2002), and recent serologic evidence also suggested that, although uncommon, *C. felis* may be a causative agent of community-acquired pneumonia (Marrie et al., 2003). If *C. felis* is zoonotic, maintenance of hygienic conditions and prompt treatment of affected cats are recommended to prevent human disease, although further investigation of the zoonotic potential of this organism is needed. Adherence to guidelines designed to protect immunodeficient people from health risks related to pet ownership should also minimize the risk of infection by *C. felis* (Greene and Levy, 2006).

DIAGNOSIS

Chlamydial infection must be differentiated from other infectious and noninfectious causes of feline conjunctivitis. Examination of Giemsa-stained conjunctival smears for chlamydial inclusions is not considered a reliable means of diagnosing feline chlamydial infection. Inclusions are often visible early in the course of infection only, if at all. Melanin granules or topical medication inclusions ("blue bodies") may be confused with chlamydial inclusions (Streeten and Streeten, 1985).

Cell culture uses fluorescent antibodies to detect intracytoplasmic chlamydial inclusions following inoculation of cell monolayers. Special chlamydial transport media containing appropriate antimicrobials are required to preserve chlamydial viability, which can be obtained from the laboratory. Isolation in cell culture is technically demanding, time-consuming, and expensive. Transportation and storage problems can affect the sensitivity of cell culture, and some samples may be toxic for cell culture monolayers. The sensitivity of culture may vary between laboratories, depending on equipment and technical expertise.

Diagnostic PCR assays are more rapid, less expensive, and in many cases more sensitive than traditional techniques such as culture. They are now used routinely for diagnosis of human chlamydial infections, and assays for *C. felis* are becoming increasingly available. With proper sample collection and storage, PCR has good sensitivity and specificity. Fluorescence-based real-time PCR assays permit quantification of organism load and may be less prone to contamination than conventional PCR (Dean et al., 2005). Samples for all PCR assays can be collected from the conjunctival sac using a saline-moistened cotton swab. Veterinarians collecting samples for PCR should contact the laboratory for sample collection and handling guidelines to minimize contamination occurring outside the laboratory and should ensure that the laboratory includes both a positive and a negative control that are subjected to the extraction process on every run.

Currently testing for chlamydiae other than *C. felis* such as *N. hartmannellae* requires broad-spectrum chlamydial PCR, which is only available in certain research laboratories. Further information on the association of these organisms with disease will be required before routine testing in cats with conjunctivitis can be recommended.

TREATMENT

Chlamydiae are susceptible to tetracyclines, erythromycin, rifampin, fluoroquinolones, and the azalide azithromycin. In contrast to popular belief, sulfonamides and chloramphenicol are ineffective against *C. felis*. Systemic antimicrobial therapy is essential because of the systemic nature of infection. Doxycycline is the treatment of choice and appears to be superior to azithromycin, even when azithromycin is administered daily (Owen et al., 2003). Rapid clinical improvement and elimination of the organism occur within 7 days of beginning treatment. In research colonies *C. felis* infection has been cleared effectively using systemic doxycycline alone for 3 weeks (5 mg/kg every 12 hours) (Sykes, Studdert, and Browning, 1999). However, in a recent study, treatment for 7, 14, and

then 21 days with doxycycline (10mg/kg every 24 hours PO) did not eliminate infection in all cats, leading to the recommendation that all cats be treated for 4 weeks with doxycycline (Dean et al., 2005). Recrudescence was noted as long as 35 days after discontinuation of therapy, suggesting that cats be retested for up to 1 month before concluding that infection had been eliminated. In some cases periods of treatment longer than 3 weeks have also been necessary to eliminate natural infections with *C. felis*. A minimum of 6 to 8 weeks of treatment, especially for cat-tery cats, has also been suggested. Regardless of the treatment course chosen, continuation of therapy for 2 weeks after resolution of clinical signs is probably warranted.

It is possible that in chronic infections the organism may be more difficult to eliminate. However, recurring cases often involve large numbers of cats and poor compliance. All cats must be treated with the full course of antimicrobials, and proper hygiene and quarantine must be maintained. This may be difficult to achieve when a problem exists in a large cat population. Concurrent infection with organisms such as FHV-1 and FCV may also be a problem, and affected animals often show an initial response to antimicrobial therapy because of resolution of secondary bacterial infections. Use of a solution comprising 1 part bleach and 32 parts detergent is recommended for general disinfection when FCV infection remains a possibility.

There is a risk of permanent teeth discoloration in kittens if tetracyclines are used in pregnant queens in the last 2 to 3 weeks of pregnancy or in kittens in the first few months of life. Doxycycline has reduced calcium-binding avidity compared with other tetracyclines, and there is little evidence to suggest that teeth discoloration occurs in kittens given doxycycline. To minimize the risk of doxycycline-induced esophagitis (and the more severe complication of esophageal stricture), doxycycline suspension should be administered, or a water bolus should be administered by syringe after tablet administration. Although penicillin is only considered inhibitory, a 4-week course of amoxicillin-clavulanic acid eliminated *C. felis* in experimentally infected cats, with no recurrence 6 months after discontinuing therapy (Sturgess et al., 2001). This may be a safe alternative to tetracyclines for the treatment of chlamydiosis in young kittens.

VACCINATION AND IMMUNITY

Although immunity to chlamydial infection is generally weak or short-lived, an apparent age-related resistance of cats to *C. felis* infection suggests that some form of protective immunity must develop eventually. Both humoral

and cell-mediated immunity appear essential for resolution of infection. Most kittens acquiring colostrum from previously exposed queens appear to be protected by maternally derived antibody until 2 to 3 months of age.

Both modified-live and inactivated cell culture vaccines have been used in the United States, either alone or in combination with feline panleukopenia, FCV, and FHV-1 components. Atypical reactions to *C. felis* vaccines such as fever, lethargy, anorexia, and lameness 7 to 21 days after vaccination have been reported in a small percentage of vaccinated cats. The chlamydial vaccine does not prevent infection or clinical signs, although the latter are generally reduced in severity. Vaccines may be of some benefit as part of a control program in catteries with endemic chlamydiosis.

Antiviral Therapy for Feline Herpesvirus

DAVID J. MAGGS, *Davis, California*

A large variety of antiviral agents are available for oral or topical treatment of cats infected with feline herpesvirus type 1 (FHV-1). Some general comments regarding these therapies follow. Knowledge of these general principles can be used to better understand antiviral pharmacology and thereby guide therapy of cats infected with FHV-1.

- No antiviral agent has been developed for FHV-1, although many have been tested for efficacy against this virus. Agents highly effective against closely related human herpesviruses are not necessarily or predictably effective against FHV-1, and all should be tested in vitro before they are administered to cats. In vitro potency is described as the drug concentration at which viral replication is suppressed by 50% (or IC_{50}). Therefore a more potent drug will have a lower IC_{50} .
- No antiviral agent has been developed for cats, although some have been tested for safety in this species. Agents with a reasonable safety profile in humans are not always or predictably nontoxic when administered to cats, and all require safety and efficacy testing in vivo.
- Many antiviral agents require host metabolism before achieving their active form. These agents are not reliably or predictably metabolized by cats, and pharmacokinetic studies in cats are required.
- Antiviral agents tend to be more toxic than do antibacterial agents since viruses are obligate intracellular organisms and co-opt or have close analogs of the host's cellular "machinery." This limits many antiviral agents to topical (ophthalmic) rather than systemic use.
- All antiviral agents currently used for cats infected with FHV-1 are virostatic. Therefore they typically require frequent administration to be effective.

The following antiviral agents have been studied to varying degrees for their efficacy against FHV-1, their pharmacokinetics in cats, and/or their safety and efficacy in treating cats infected with FHV-1.

IDOXURIDINE

Idoxuridine is a thymidine analog originally developed for treatment of humans infected with herpes simplex virus (HSV) type 1. Following intracellular phosphorylation, it competes with thymidine for incorporation into viral deoxyribonucleic acid (DNA), rendering the resultant virus incapable of replication. However, apparently

it does this less effectively in FHV-1 than in HSV-1, with its reported IC_{50} ranging from 4.3 to 6.8 μ M. Idoxuridine is a nonspecific inhibitor of DNA synthesis, affecting any process requiring thymidine. Therefore host cells are similarly affected, systemic therapy is not possible, and corneal toxicity can occur. It has been used as a topical (ophthalmic) 0.1% solution or 0.5% ointment. This drug is reasonably well tolerated by most cats and seems efficacious in many. It is no longer available commercially in the United States but can be obtained from a compounding pharmacist. It should be applied to the affected eye five to six times daily.

VIDARABINE

Vidarabine is an adenosine analog that, following triphosphorylation, appears to affect viral DNA synthesis by interfering with DNA polymerase. However, like idoxuridine, vidarabine is nonselective in its effect and thus is associated with notable host toxicity if administered systemically. Because it affects a viral replication step different from that targeted by idoxuridine, vidarabine may be effective in patients with a disease that seems resistant to idoxuridine. As a 3% ophthalmic ointment, vidarabine often appears to be better tolerated than many of the antiviral solutions. The reported IC_{50} for FHV-1 is 21.4 μ M. Where it is not available commercially, it can be obtained from a compounding pharmacist. Like idoxuridine, it should be applied to the affected eye five to six times daily.

TRIFLURIDINE

Trifluridine (or trifluorothymidine) is a nucleoside analog of thymidine. Its specific mechanism of action against HSV-1 (for which it was developed) is incompletely understood and has not been studied in FHV-1. Following intracellular phosphorylation it reduces DNA synthesis via inhibition of thymidylate synthetase. Trifluridine is too toxic to be administered systemically, but topical administration is considered one of the most effective treatments for HSV-1 keratitis. This is in part because of its superior corneal epithelial penetration. It is also one of the more potent antiviral drugs for FHV-1, with a reported IC_{50} of 0.67 μ M. It is available commercially in the United States as a 1% ophthalmic solution that should be applied to the affected eye five to six times daily. Unfortunately it is expensive and is often not well tolerated by cats, presumably because of a stinging reaction reported in humans.

ACYCLOVIR

Acyclovir is the prototype of a group of antiviral drugs known as acyclic nucleoside analogs. Members of this group of antiviral agents all require three phosphorylation steps for activation. The first of these steps must be catalyzed by a viral enzyme, thymidine kinase. This property increases their safety and permits them to be administered systemically to humans. However, the activity of this enzyme in FHV-1 has not been verified. The second and third phosphorylation steps must be performed by host enzymes, which may not be present in cats or may not be as effective in cats as they are in humans. This knowledge helps explain why antiviral agents developed for humans infected with HSV-1 may not be safe or effective when administered to cats infected with FHV-1. The IC_{50} reported for acyclovir against FHV-1 ranges from 57.9 to 248.7 μM , which is much higher than that reported for HSV-1. In addition to relatively low antiviral potency against FHV-1, acyclovir has poor bioavailability and is potentially toxic when administered systemically to cats. Oral administration of 50 mg/kg of acyclovir to cats was associated with peak plasma levels of only 33 μM (approximately one third the IC_{50} for this virus). Common signs of toxicity are referable to bone marrow suppression.

However, acyclovir is also available as a 3% ophthalmic ointment in some countries. In one study in which a 0.5% ointment was used five times daily, the median time to resolution of clinical signs was 10 days. Cats treated only three times daily took approximately twice as long to resolve and did so only once therapy was increased to five times daily. Taken together, these data suggest that very frequent topical application of acyclovir may produce concentrations at the corneal surface that exceed the reported IC_{50} for this virus but are not associated with toxicity. There are also in vitro data suggesting that interferon exerts a synergistic effect with acyclovir that could permit an approximately eightfold reduction in acyclovir dosage. In vivo investigation and validation of these data are needed.

VALACYCLOVIR

Valacyclovir is an acyclic nucleoside analog and a prodrug of acyclovir, which in humans and cats is more efficiently absorbed from the gastrointestinal tract compared with acyclovir and is converted to acyclovir by a hepatic hydrolase. Its safety and efficacy have been studied in cats. Plasma concentrations of acyclovir that surpass the IC_{50} for FHV-1 can be achieved after oral administration of this drug. However, in cats experimentally infected with FHV-1, valacyclovir induced fatal hepatic and renal necrosis, along with bone marrow suppression, and did not reduce viral shedding or clinical disease severity. Therefore, despite its superior pharmacokinetics, valacyclovir should not be used in cats.

GANCICLOVIR

Ganciclovir is another acyclic nucleoside analog that also requires triphosphorylation to achieve its active form. Like acyclovir, the first phosphorylation step is mediated

by viral thymidine kinase. Despite these similarities, it appears to be approximately tenfold more effective against FHV-1 compared with acyclovir, with its IC_{50} ranging from 5.2 to 12.5 μM . It is available for systemic (intravenous or oral) and intravitreal administration in humans, where it is associated with greater toxicity than acyclovir. Toxicity is typically evident as bone marrow suppression. There are no reports of its safety or efficacy in cats.

PENCICLOVIR

Penciclovir is a nucleoside deoxyguanosine analog with a mechanism of action similar to that of acyclovir and potent antiviral activity for a number of human herpesviruses. It too requires viral and cellular phosphorylation and yet has a relatively low IC_{50} for FHV-1 (13.9 μM). It is available as a dermatologic cream for humans that should not be applied to the eye. Although there are some data regarding administration of famciclovir to cats (which is converted to penciclovir), in vivo studies of safety or efficacy of penciclovir in cats are lacking, and at this time its use in cats cannot be recommended.

FAMCICLOVIR

Famciclovir is a prodrug of penciclovir; however metabolism of famciclovir to penciclovir in humans is complex and requires di-deacetylation, predominantly in the blood, and subsequent oxidation to penciclovir by aldehyde oxidase in the liver. Unfortunately hepatic aldehyde oxidase activity is nearly absent in cats. This necessitates cautious extrapolation to cats of data generated in humans. In fact, a recent study of famciclovir in normal cats suggests that the pharmacokinetics of this drug are extremely complex and likely result from nonlinear famciclovir absorption, metabolism, or a combination of the two. Despite this, some early evidence (Thomasy et al., 2007) and anecdotal reports suggest that famciclovir is most effective in some cats with suspected herpetic disease. Further studies of the pharmacokinetics, safety, and efficacy of this drug are required before dosage rates and frequency can be recommended.

CIDOFOVIR

Cidofovir is a relatively new cytosine analog that requires two host-mediated phosphorylation steps without virally mediated phosphorylation. Its safety arises from its relatively high affinity for viral DNA polymerase compared with human DNA polymerase. The IC_{50} reported for FHV-1 ranges from 11 to 21.5 μM . It is available in injectable form in the United States and is administered intravenously to humans infected with herpesviruses, principally cytomegalovirus. This drug has also been topically applied as a 0.5% or 1% solution in experimental animal models of human herpetic keratoconjunctivitis and found to be as effective when administered only twice daily as trifluridine was when administered four to nine times daily. This is believed to be because of the long tissue half-lives of the metabolites of this drug. Clearly an antiviral drug that could be applied less frequently than the presently available agents would offer marked advantages in veterinary ophthalmology. The efficacy of a 0.5% solution applied

topically twice daily to cats experimentally infected with FHV-1 was associated with reduced viral shedding and clinical disease in a recent study (Fontenelle et al., 2008). There are occasional reports of its experimental topical use in humans associated with stenosis of the nasolacrimal drainage system components; as yet it is not available commercially as an ophthalmic agent in humans. Therefore at this stage there are insufficient data to support its long-term safety as a topical agent in cats.

SUMMARY

Currently over 40 antiviral compounds are licensed for clinical use or in advanced clinical trials in humans. In vitro studies have now demonstrated that a subset of these drugs also have sufficient efficacy against FHV-1 to warrant further clinical investigation. However, the more severe and more frequent occurrence of toxicity associated with antiviral drugs, along with the fact that many require host metabolism to activate them, means that very careful and thorough in vivo testing of these drugs in normal cats and cats infected with FHV-1 is necessary to assess their pharmacokinetics and efficacy, respectively. Reliance on data generated when these drugs were

administered to a different species, via a different route, and for treatment of a different virus is unwise.

CHAPTER 259

Episcleritis and Scleritis in Dogs

ANNA R. DEYKIN, *Queensland, Australia*

PPrimary inflammatory diseases of the sclera and episclera are relatively uncommon but important conditions in canine practice. The pathophysiology of these diseases is poorly understood, and nomenclature can be confusing. These diseases often present as a “red eye” and can be similar to many other ocular conditions. In dogs, unlike in humans, these diseases do not appear to be associated with any systemic disease.

ANATOMY

The sclera, along with the cornea, forms the outer fibrous tunic of the eye. This dense connective tissue layer is composed of collagen fibers arranged in bundles, elastic fibers, and blood vessels. It merges with the cornea at an area called the limbus. The episclera is a thin collagenous, vascular membrane between the sclera and the overlying Tenon’s capsule and conjunctiva. It begins at the limbus and extends posteriorly to the insertions of the extraocular muscles. The episclera is considered part of the sclera.

Tenon’s capsule is a dense connective tissue layer that attaches anteriorly near the limbus and blends posteriorly with the fascia of the extraocular muscles. It has also been referred to as the superficial episclera.

Episcleritis

Clinically episcleritis seems to be a much more common entity than scleritis. Although inflammation of the episclera may have several clinical appearances, affected patients tend to have nonpainful eyes. The lesion may be simple (or diffuse) or nodular (or proliferative).

Simple Episcleritis

This is seen as a diffuse area of inflammation, affecting a sector or larger area of the episclera. The episcleral vessels become engorged, and the affected area is thickened. These changes begin at the limbus, extending back to near the insertions of the extraocular muscles. It is this thickened or raised area that helps differentiate simple episcleritis from

other causes of a red eye such as glaucoma and uveitis. There may be perilimbal corneal edema and some superficial corneal vascularization. The exposed area of episclera at the lateral canthus is the most commonly affected area.

Nodular Episcleritis

Many descriptive labels have been given to nodular inflammatory disease of the episclera, including fibrous histiocytoma, nodular fasciitis, nodular granulomatous episclerokeratitis (NGE), and proliferative keratoconjunctivitis. These terms seem to apply to possibly the same or similar conditions in which the lesion is proliferative or nodular. Most of these episcleral lesions present as slowly progressive pink nodules located on or near the limbus and sometimes infiltrating the cornea. Most of the published literature refers to these lesions in the collie breed. Collies seem to be the most commonly affected breed in the United States, but in other countries this breed predisposition does not seem so overt.

Through common usage, the term *NGE* is now used for nodular episcleritis in the collie breed, which may be different from nodular episcleritis in other breeds. *NGE* in the collie tends to manifest as multiple nodules affecting both eyes. The nodules tend to be on the lateral limbus and usually extend onto and into the cornea. When the lesions involve the cornea, an arc of lipid infiltrate may be seen in the cornea adjacent to the lesion. The third eyelid also may be involved. In other breeds lesions are usually singular without third eyelid involvement and may be more correctly referred to as nodular episcleritis. Inflammatory episcleral disease is thought to be immune mediated in most cases. There is no other concurrent ocular or systemic disease. Intraocular pressure is normal, and there is no coincident uveitis or ocular discharge.

The inflammatory process in patients with either episcleral or scleral involvement is consistently characterized as chronic granulomatous inflammation, with the main

cell types being histiocytes, lymphocytes, and plasma cells. Abundant reticulin fiber formation is seen. This suggests a chronic reaction to a persistent antigen. However, no organisms have been identified in any cases of canine episcleritis or scleritis, and the inflammatory response may be directed toward degenerating collagen. In episcleritis the inflammatory reaction is limited to just the episclera, with anterior extension into the cornea seen in some cases. With scleritis inflammation involves the full scleral thickness. Simple episcleritis is characterized by nongranulomatous inflammation with lymphocytic and plasma cell infiltrates.

Diagnosis of Episcleral Inflammatory Disease

Despite the highly suggestive clinical appearance, biopsy is usually recommended to confirm a diagnosis of *NGE*, nodular episcleritis, or simple episcleritis. Other causes of red eye need to be ruled out by performing a thorough ophthalmic examination, including tonometry (see Chapter 255). Biopsy should then be performed to differentiate nodular episcleral disease from neoplastic disease such as squamous cell carcinoma or lymphoma and causes of granulation tissue formation such as trauma or a foreign body.

Treatment of Episcleral Inflammatory Disease

Topically or systemically administered immunomodulatory treatment can be used in patients with episcleritis (see also Chapter 250). Both routes may be needed in the initial stages of treatment. Once the clinical signs are controlled with concurrent therapy, systemic treatment may be withdrawn. This approach may minimize systemic effects of antiinflammatory and immunosuppressive medications. Simple episcleritis is often a monophasic disease, and ongoing treatment may not be required. The nodular forms of the disease may respond well to treatment, but recurrences are commonly reported (Table 259-1).

Table 259-1

Drugs Used To Treat Episcleritis

Drug	Dose	Comments
1% Prednisolone acetate ophthalmic drops	1 drop q6h; then reduce to minimum dose possible	May be sufficient for simple episcleritis and mild nodular episcleral disease
0.1% Dexamethasone ophthalmic drops	1 drop q6h; then reduce to minimum dose possible	May be sufficient for simple episcleritis and mild nodular episcleral disease
Cyclosporine 0.2% ointment; 1% or 2% suspension	Small amount q12h	Useful for nodular episcleral disease in combination with topical and/or systemic corticosteroids
Prednisolone	1-2 mg/kg/day PO; then reduce to minimum dose	Possibly the most effective treatment for all types of episcleral and scleral disease
Azathioprine	2 mg/kg q24h; then reduce to 1 mg/kg and taper further to every other day or twice weekly	Effective treatment for <i>NGE</i> but can have side effects Useful for dogs that cannot tolerate corticosteroids
Tetracycline	Over 10 kg: 500 mg q8h	Useful treatment combination with very few side effects long term; may take a long time (6 weeks) for clinical response
Niacinamide	Under 10 kg: 250 mg q8h Over 10 kg: 500 mg q8h Under 10 kg: 250 mg q8h	
Triamcinolone acetonide, 6 mg/ml	0.1-0.2 ml intralesionally	Medium-acting corticosteroid
Methylprednisolone acetate, 20 mg/ml	0.1-0.2 ml intralesionally	Long-acting corticosteroid; may see granuloma formation at injection site
Doxycycline	2.5 mg/kg q12h	

Corticosteroids are commonly used in the treatment of all forms of episcleritis and may be given topically, systemically or intralesionally. Simple episcleritis may respond to topical corticosteroids alone. Nodular forms of episcleritis may also respond to topical corticosteroids but often require systemic treatment concurrently. Surgical debulking and intralesional corticosteroids may have a role in refractory cases. Topical medications used include 1% prednisolone acetate suspension or 0.1% dexamethasone suspension. Treatment may need to be as frequent as every 6 hours initially. Depending on response, systemic corticosteroids such as prednisolone may also be used, initially at a dose of 1 to 2 mg/kg every 24 hours. Intralesional corticosteroids can be useful in the treatment of localized or nodular disease. Methylprednisolone acetate or triamcinolone acetonide can be injected directly into or just adjacent to the lesion using a 27- to 30-gauge needle. This can usually be done with topical anesthesia, with or without sedation.

Topical cyclosporine therapy may also be useful in episcleritis, often in combination with topical or systemic corticosteroids. Cyclosporine is an immunosuppressive agent that inhibits T lymphocyte activation. It is available commercially for veterinary topical use as a 0.2% ointment or can be compounded as 1% or 2% suspensions suitable for topical ophthalmic use.

Azathioprine has been reported to be an effective treatment of NGE in collies. Azathioprine is an immunosuppressive drug that affects rapidly dividing cells and also inhibits T cell function. It should be used with caution since it can have severe side effects such as myelosuppression and hepatotoxicosis. Complete blood counts and serum biochemistry panels should be monitored approximately every 2 weeks during therapy, and treatment stopped if white blood cell counts start to fall. The recommended dosage of azathioprine is 2 mg/kg every 24 hours until the lesions have regressed and then reducing to 1 mg/kg every 24 hours and tapering to every second day or once weekly. Therapy has been discontinued in some cases with no recurrence. Because of the risk of serious side effects and the need for constant monitoring, azathioprine is usually only used in cases that have failed to respond to topical medications or systemic or intralesional corticosteroids. It may also be used in dogs that cannot tolerate corticosteroids.

More recently the use of tetracycline and niacinamide has been reported in the treatment of granulomatous inflammatory skin disease; this may be an important treatment regime in cases of episcleral disease in which the side effects of corticosteroids and azathioprine are a problem. The recommended dosage is 500 mg of tetracycline every 8 hours and 500 mg of niacinamide every 8 hours for dogs over 10 kg. For dogs under 10 kg, the dose is 250 mg of each drug at the same dosage frequency. Doxycycline can be used instead of tetracycline. Recommended dose is 2.5 mg/kg q12h. Treatment usually has to be continued for at least 6 weeks before a clinical response may be seen. This regimen has fewer side effects, especially if long-term therapy is needed.

Cryosurgery has been described for the treatment of NGE in collies, usually after surgical debulking.

Scleritis

Scleritis is seen less commonly than episcleritis in dogs. It can be a difficult disease to recognize clinically since it may resemble other ocular inflammatory diseases and often involves concurrent inflammation of adjacent structures. As with episcleritis, the nomenclature surrounding this disease has been confusing. Traditionally scleritis in humans and dogs has been divided into nonnecrotizing and necrotizing forms. Nonnecrotizing scleritis is seen more commonly than necrotizing scleritis in dogs. The term *nonnecrotizing scleritis* has been used to refer to nodular episcleritis. Scleritis in humans is often associated with systemic autoimmune disorders. Although necrotizing scleritis in dogs was associated with seropositivity to *Ehrlichia canis*, in general concurrent systemic disease has not been identified readily in dogs with scleritis.

The anterior sclera is more commonly affected, but inflammation can extend caudally where it is less easily visualized. The granulomatous inflammatory infiltrate tends to be full thickness; therefore secondary nongranulomatous inflammation of the subjacent anterior uvea, choroid, or retina occurs in many cases. Pain is usually associated with scleritis because of the presence of sensory nerve endings in the sclera where the extraocular muscles attach.

Treatment of Scleritis

Topical corticosteroids may have limited value in scleritis, especially when it is more diffuse and affects more than just the anterior sclera. Systemic corticosteroids and azathioprine, as described for episcleritis, may be more useful. Scleritis is generally more difficult to treat than inflammatory episcleral disease, and relapse is more likely.

Qualitative Tear Film Disturbances of Dogs and Cats

CHRISTINE C. LIM, *Davis, California*

Patients with chronic keratitis and/or conjunctivitis are seen commonly in small animal practice. Many such patients do not have a clinically obvious cause of their signs, as examination of the eyelids reveals no conformational or functional defects and Schirmer's tear test (STT) values fall within limits of normal. Chronic keratoconjunctivitis in these patients may result, at least in part, from deficiencies in components of the tear film other than the aqueous fraction. Such disorders are the focus of this chapter. For more information on aqueous deficiency of the tear film, see Section XII on Evolve.

ANATOMY AND PHYSIOLOGY

The precorneal tear film is a trilaminar structure approximately 7 to 10 μm thick. In addition to the abundant middle aqueous layer, there is an outer lipid layer and an inner mucin layer. Although often forgotten, both of these layers are crucial for optical clarity and surface ocular health. Although tears are responsible for both conjunctival and corneal surface health, the lack of blood supply of the cornea makes effects of tear deficiency more notable there than on the conjunctiva; however, conjunctival effects remain important. Alteration of amount or quality of the lipid or mucin layer is referred to as a qualitative tear film abnormality (Fig. 260-1).

The lipid layer comprises the outermost 0.1 μm of the precorneal tear film and is composed of a mixture of polar and nonpolar lipids. The feline lipid layer resembles that of humans, being thinner than that of the dog. The meibomian or tarsal glands, located within the eyelids, produce this layer of the tear film. The meibomian gland openings can be seen along the eyelid margins and should always be assessed during routine ophthalmic examination. Tear film lipid, or meibum, occurs as a liquid at body temperature, allowing it to be spread across the surface of the precorneal tear film with eyelid movement. The main function of this layer is to minimize evaporation of the precorneal tear film between blinks. Meibum also decreases surface tension of the tear film, thereby maintaining tear film stability and a smooth, optically clear surface.

The innermost 1-2 μm of the precorneal tear film is composed of mucins. The majority of the ocular mucins are secreted by the conjunctival goblet cells; however, a lesser contribution is also made by the epithelial cells of the conjunctiva and cornea. Although goblet cells are located throughout the conjunctiva, these cells are particularly concentrated within the ventromedial conjuncti-

val fornices. Along with meibum, mucin plays an integral role in maintaining tear film stability by decreasing the surface tension of the tear film. Mucin also binds tear film contaminants such as particulate matter and bacteria and aids in maintaining an optically smooth surface by filling irregularities of the corneal epithelial surface. The viscous nature of mucin also promotes adherence of the hydrophilic tear film to the hydrophobic corneal epithelium.

PATHOPHYSIOLOGY

Because of contributions from the lipid and mucin layers, the tear film maintains itself as a continuous film over the cornea. During each blink fresh meibum and mucin are spread across the surface of the globe. At the same time, contaminants from the precorneal tear film are drawn into the lacrimal drainage apparatus. However, if the eyelids remain open for a prolonged period of time, a combination of tear film thinning and increased tear film contamination results in breaks within the tear film, leaving dry spots on the corneal surface. Rapid evaporation of the tear film in turn establishes an osmotic gradient that further dries and damages the corneal surface. The time between eyelid opening and the first appearance of a dry spot within the precorneal tear film is referred to as the tear film breakup time (TFBUT). In health, blinking generally occurs before the breakup of the tear film.

Clinical disease occurs when TFBUT is shorter than the time between blinks. Shortened TFBUT results from abnormalities in either the lipid or mucin portion of the tear film, which destabilizes the tear film, thereby causing breaks within the tear film and the formation of dry spots on the corneal surface. These qualitative tear film abnormalities may either predispose to or result from other disease processes. Regardless, because the tear film may be considered an extension of the cornea and conjunctiva, alterations of the tear components often induce corneal and conjunctival damage. Keratitis may manifest clinically with any combination of superficial corneal vascularization, edema, fibrosis, or melanosis. Corneal ulcers, particularly indolent ulcers, may also be present (see Section XII on Evolve). Conjunctival hyperemia is usually present and may be accompanied by chemosis. Affected animals show varying degrees of blepharospasm and, ironically, lacrimation.

Although qualitative tear film abnormalities may occur in any patient, some conditions predispose to these problems. A high incidence of qualitative tear film abnormalities has been documented in diabetic dogs. In humans

Fig. 260-1 Ultrastructure of the preocular tear film of dogs and cats and the various sites of production, including the goblet cells, lacrimal gland, gland of the third eyelid, tarsal (meibomian) glands. (From Grahn BH, Storey ES: Lacrimostimulants and lacrimomimetics. In *Veterinary Clinics of North America: Small Animal Practice*, May 2004, Vol 34, Issue 3, Fig 1, p. 740.)

a higher incidence of tear film abnormalities is documented with increasing age, especially in women. When compared to dolichocephalic and mesocephalic animals, brachycephalic breeds are particularly at high risk for development of qualitative tear film abnormalities. This risk likely relates to breed-related exophthalmia, decreased corneal sensitivity, low blink frequency, lagophthalmos, a relatively thinned tear film, increased contamination of the tear film, and an impaired ability to clear tear film contaminants.

Abnormalities in the Lipid Layer

Although congenital absence of meibomian glands has been documented in humans, it has yet to be documented in veterinary patients. However, depending on its severity, eyelid agenesis may result in a reduced number of meibomian glands.

More commonly lipid abnormalities arise as a consequence of blepharitis, especially if it causes secondary meibomianitis (Fig. 260-2). Bacterial (especially *Staphylococcus* spp.), allergic, mycotic, and parasitic (especially *Demodex* spp.) dermatitis; autoimmune disease (pemphigus); endocrine dermatoses; and eyelid neoplasia all may cause blepharitis and, to varying degrees, meibomianitis. Inflammation of the eyelids and thus the meibomian glands alters the structure of its lipid products such that meibum can become directly toxic to the ocular surface. In addition, meibum becomes a paste rather than a fluid, causing obstruction of the glands, further meibomian gland dysfunction, and inefficient spread of lipid over the tear surface.

Abnormalities in the Mucin Layer

In addition to causing tear film instability, mucin deficiency may lessen the ability of the tear film to trap and remove particulate and microbial contaminants from

Fig. 260-2 Photograph of the right eye of an 11-year-old female spayed golden retriever. Note the inflamed, thickened upper eyelid, copious mucoid ocular discharge, and conjunctival hyperemia. (Photograph courtesy the UC Davis Veterinary Ophthalmology Service.)

the ocular surface, thereby predisposing the conjunctiva and cornea to secondary infection. Mucin deficiencies occur spontaneously in dogs and cats. They may also occur secondary to conjunctivitis. Squamous metaplasia and decreased goblet cell counts occur in the presence of inflammatory infiltrates following infection with feline herpesvirus (FHV-1) in cats with corneal sequestrum and dogs with keratoconjunctivitis sicca (KCS). Given the association between inflammatory surface ocular disease and mucin deficiency, animals diagnosed with conjunctivitis should be assessed for concurrent tear film instability.

DIAGNOSTIC TESTING

A number of tests may assist in diagnosing abnormalities of the lipid layer; however, for the most part these examinations have been developed for humans and are not yet commonly used or validated for veterinary patients. Of these diagnostic studies, meibometry shows promise for assessing the lipid layer of the tear film in animals. This test is performed by applying tape to the eyelid margins and evaluating the change in optical density of the tape. Although normal meibometry values have been established for dogs, this technique is not yet readily available for clinical use. Currently, detection of lipid abnormalities relies on clinical examination alone. When blepharitis is present, it is generally evident as edema, hyperemia, maceration, alopecia, or excoriation of the eyelids, often in association with ocular discharge. Inspissated meibum may also be evident at the gland orifices, and digital manipulation often yields further extrusion of this substance. When these clinical signs are present, alterations of the lipid layer can be assumed.

Although lipid abnormalities may be assumed in the presence of blepharitis, mucin deficiencies are less clinically obvious, and further testing is required. Of the many available diagnostic tests for evaluating the mucin layer, the TFBUT is perhaps the most noninvasive and simple to perform. The TFBUT is one of the more repeatable measures of tear film stability and is extremely useful as a screening test for qualitative tear

film abnormalities. In the absence of blepharitis (and therefore lipid abnormalities), TFBUT can be considered a measure of the function of the mucin portion of the tear film.

The TFBUT is a diagnostic study that measures the time elapsing between eyelid opening and the appearance of the first dry spot within the tear film. This interval should be assessed in a darkened room. Fluorescein is first instilled into the conjunctival sac, and the eyelids are closed immediately. When the eyelids are opened, timing begins, and the examiner then observes a portion of the corneal surface, usually the dorsolateral aspect, using the cobalt blue light and magnification. Ideally the 16× magnification available with a slit-lamp biomicroscope is used, but magnifying loupes may also be useful. Magnification is essential to observe the expected changes in the tear film. The tear film overlying the cornea initially appears homogeneously green. However, when the tear film breaks, black spots appear within this film. Timing ceases at the appearance of the first black spot. Average TFBUTs for normal dogs and cats have been reported as 19.7 ± 5 seconds and 16.7 ± 4.5 seconds, respectively. By comparison, TFBUTs as short as 1 second are seen in cats with mucin deficiency.

Goblet cell enumeration is a more reliable indicator of mucin deficiency than direct measurements of tear mucin content. Conjunctival biopsy for documentation of goblet cell numbers confirms mucin-deficient qualitative tear film disturbances. Because of the predominance of goblet cells within the ventromedial conjunctival fornix, this is the recommended site for conjunctival biopsy. Using local anesthesia, conjunctival biopsy can be performed easily in a conscious patient. After placing a drop of 0.5% proparacaine into the conjunctival fornix, cotton-tipped applicators soaked in 2% lidocaine gel are then held against the intended biopsy site for approximately 1 minute. Care should be taken not to apply excess lidocaine to the cornea because of its toxic effects. Small tissue forceps such as Bishop-Harmon forceps are used to elevate the conjunctiva, and a 2- to 3-mm section of conjunctiva is removed using small scissors such as Stevens tenotomy scissors (Fig. 260-3). The tissue sample should include substantia propria in addition to conjunctival epithelium. Care must be taken when obtaining and handling the sample because excessive manipulations may cause goblet cells to release their contents and become less recognizable. The tissue sample should be placed immediately in 10% formalin for histologic analysis. Goblet cells are quantified by determining the number of goblet cells within a standardized length of epithelial cells. Normal goblet cell ratios appear to be above 0.3 in the dog and 0.6 in the cat.

Once a qualitative tear film abnormality has been diagnosed, an attempt to identify the underlying cause, if any, should always be made. Meticulous examination of the adnexa will identify or rule out contributing eyelid abnormalities. Depending on clinical presentation, patients with blepharitis should be screened for bacterial, mycotic, or parasitic infections; autoimmune, allergic, endocrine, or dermatologic disorders; and neoplasia. Cats with conjunctivitis should be screened for FHV-1, *Chlamydomydia felis*, and *Mycoplasma* spp. In dogs specific

differential diagnoses for conjunctivitis include allergic, viral (distemper), fungal (blastomycosis), parasitic (*Thelazia*), rickettsial, or neoplastic causes, along with KCS and pannus.

THERAPY

Treatment for qualitative tear film abnormalities should address the underlying cause for the abnormality, the specific lipid or mucin abnormality, and any disease occurring secondary to the tear film deficiency. Treatment of underlying disease obviously will be tailored to the specific condition. Should secondary ulcerative keratitis be present, antibiotic prophylaxis should be initiated, preferably with a well-tolerated broad-spectrum ophthalmic formulation such as a neomycin-polymyxin B-bacitracin combination applied topically between two and four times daily.

Tear Replacement Products

Treatment of specific lipid or mucin abnormalities relies on the use of tear replacement agents. Many available products differ in their suitability for specific tear film abnormalities. In general, water-soluble formulations are used for mucin deficiencies, whereas ointments are preferred for lipid abnormalities. Lacrimostimulant therapy is not indicated if the aqueous phase is present in adequate amounts. Instead lacrimomimetics, which replace specific portions of the tears, should be used and are complimentary to other topical therapies. Additional considerations are the type or presence of preservative and the specific active ingredients (especially viscosity agents) added to the tear replacement product (see below).

Preservatives are added to all multidose vials to prolong the shelf life of the product. Unfortunately preservatives may induce allergic reactions, and excessive application is toxic to the corneal epithelium, especially

if the cornea is already compromised. Patients may differ in their tolerance of ophthalmic products. If one tear substitute is not well accepted, another formulation should be tried. In particular, patients that exhibit signs of irritation after application of preservative-containing solutions should be switched to preservative-free tear substitutes. A preservative-free solution is preferred when corneal and conjunctival disease is moderate to severe or when dose frequency exceeds six times per day. The disadvantage of preservative-free solution lies in its added expense and single-dose packaging.

Viscosity agents are included in tear replacements to increase corneal surface retention time and promote cohesiveness of the tear film. Some common viscosity agents include polyvinyl alcohol, celluloses (methylcellulose, hydroxymethylcellulose), viscoelastics (sodium hyaluronate, chondroitin sulfate), and petrolatum. Of these, 0.1% sodium hyaluronate, high-concentration (1% to 2%) methylcellulose formulations, and polymer formulations (dextran, polyvinylpyrrolidone, polymer 940) demonstrate mucinomimetic properties and have a superior ability to improve tear film stability and wetting of the corneal surface. Therefore these viscosity agents should be included in the treatment regimen when a mucin deficiency has been diagnosed. Petrolatum, lanolin, and mineral oil most closely mimic the lipid layer of the tear film and should be used when lipid abnormalities are present. Generally ocular lubricants containing these materials are formulated as ointments, producing superior corneal retention time. This allows less frequent application (three to four times daily) than ophthalmic solutions (four to six times daily or more). Because of increased corneal contact time, it is recommended that ophthalmic ointments rather than solutions be applied to the eyes at bedtime, especially if the patient sleeps with the eyelids partially open.

Following improvement in clinical signs, tear replacement therapy may be discontinued in some patients. However, some patients require lifelong tear substitution for control of ocular disease.

Cyclosporine

Cyclosporine is an immunomodulator most commonly prescribed for the treatment of KCS. However, in addition to its direct stimulatory effect on the lacrimal gland, cyclosporine also has mucinogenic properties. Therefore, even in absence of aqueous deficiency, cyclosporine should be considered when mucin abnormalities are present. Cyclosporine is available commercially as a 0.2% ophthalmic ointment or may be compounded as suspensions in a variety of oils. Based on observations that the therapeutic effects of cyclosporine decrease over a 12-hour period, the drug is generally administered twice daily. Although therapy for KCS is lifelong (because of the immune-mediated nature of this disease), cyclosporine therapy may be discontinued when used to treat a specific qualitative tear film disorder. Cyclosporine exhibits its maximum mucinogenic effect after 2 weeks of treatment, and may be discontinued 2 weeks after resolution of clinical signs.

Tetracyclines

Tetracycline antibiotics have proven effective in the management of chronic blepharitis, independent of any direct antibacterial effects. Tetracyclines decrease lipase production by ocular flora, thereby decreasing the release from the meibomian glands of lipid degradation products that are toxic to the corneal epithelium. Consequently, these drugs represent another tool for the treatment of tear lipid abnormalities. Tetracyclines are available in topical and oral formulations. Oxytetracycline and tetracycline are constituted as ophthalmic ointments and solutions and are administered three to four times daily, depending on the severity of the blepharitis. In dogs and cats oral tetracycline is generally dosed at 20 mg/kg two to three times daily, and oral doxycycline at 5 to 10 mg/kg one to two times daily. Cats should receive doxycycline as a suspension rather than a tablet because of the risk of esophageal damage, including stricture. Although no specific guidelines are published, therapy should continue for about 1 week beyond the resolution of clinical signs, which can sometimes be as long as 6 to 8 weeks.

Other Treatments

Although medical therapy is the mainstay of treatment for qualitative tear film deficiencies, surgical and supportive measures are also indicated in some cases. For example, the application of warm compresses to inflamed eyelids two to three times daily eases patient discomfort and assists with drainage of inspissated meibum. Gentle removal of any dried ocular discharge with a warm, damp cloth also improves patient comfort and reduces moist blepharitis. Any eyelid abnormalities should be surgically corrected. For example, removal of distichia and ectopic cilia, or a blepharoplasty for correction of entropion, nasal fold trichiasis, or lagophthalmos may remove the underlying cause of many qualitative tear film abnormalities.

Qualitative tear film disorders should be considered in cases of keratoconjunctivitis when the STT is normal and no obvious etiology is evident on ophthalmic examination. Diagnostic testing as described above is relatively simple to perform and can be completed in most general practices. Treatment is aimed at the underlying disease, replacement of the deficient tear film component, and the keratoconjunctivitis arising from the tear film deficiency. Although therapy often can be terminated after resolution of the tear abnormality, many patients require treatment for extended periods of time.

CHAPTER 261

Nonhealing Corneal Erosions in Dogs

ELLISON BENTLEY, *Madison, Wisconsin*

Nonhealing corneal erosions (or ulcers) in dogs are commonly encountered in general clinical practice and are defined as any corneal erosion that fails to heal in an appropriate amount of time. Most traumatic erosions in dogs are uncomplicated and heal in less than a week with no sequela and minimal scarring. Any erosion that does not follow this simple course or does not exhibit significant improvement in this time period should be considered a nonhealing erosion. Specific disorders may underlie nonhealing erosions. Successful therapy involves directing treatment to the underlying cause. In other cases nonhealing erosions are caused by spontaneous chronic corneal epithelial defects, which generally require specific treatment to bring about healing.

DIAGNOSIS

A patient with an erosion that either fails to heal or enlarges should be examined carefully to determine the underlying cause of impaired wound healing. Numerous factors can delay wound healing, including mechanical trauma from lid masses, entropion, or foreign bodies; secondary infection; corneal exposure caused by paralysis of the lids; exophthalmos; buphthalmos; tear film abnormalities; conformational abnormalities resulting in lagophthalmos; or corneal edema.

Corneal edema may be associated with endothelial dysfunction and loss of the normal regulation of corneal hydration. With chronic corneal stromal edema the epithelial cells lose their firm adhesion to the underlying stroma, and epithelial bullae form (bullous keratopathy), which then rupture, leading to chronic corneal epithelial defects.

Spontaneous chronic corneal epithelial defects (SCCEDs) do not have any obvious underlying cause and

occur only in middle-aged dogs, with most studies demonstrating an average age of 8 to 9 years old. In contrast, an underlying cause of a nonhealing erosion can usually be found in dogs less than 5 years of age. SCCEDs are also known as *indolent erosions/ulcers*, boxer ulcers/erosions, persistent corneal erosions, refractory corneal ulcers, nonhealing erosions, and idiopathic corneal erosions. The instigating cause is likely to be superficial trauma, although this is documented infrequently in dogs. Dogs with diabetes mellitus are also predisposed. In SCCEDs the epithelium begins to migrate over the corneal stroma, but the basement membrane is lost, and normal epithelial adhesion complexes do not reform, resulting in delayed wound healing.

Clinically SCCEDs have a characteristic loose rim of epithelium surrounding the corneal defect. This ring is demarcated by a diffuse, less intense ring of fluorescein staining surrounding the defect. SCCEDs are superficial lesions with no loss of stromal substance. Stromal loss indicates a more severe process, is typically infectious, and should be managed accordingly (see Ulcerative Keratitis on Evolve). The degree of blepharospasm, epiphora, and corneal neovascularization varies tremendously in SCCEDs; and central corneal lesions may persist for weeks to months with no vascular response. Vascularization occurs more commonly in peripheral lesions. If corneal edema is present, it is confined to the area of the erosion. Diffuse corneal edema, particularly if present before the onset of the erosions, indicates that the primary problem is likely to be endothelial, with secondary corneal edema and bullous keratopathy. Endothelial degenerations or dystrophies are often bilateral; thus a nonhealing erosion in a patient with corneal edema in both eyes also suggests that bullous keratopathy is the underlying problem rather than SCCEDs. This chapter focuses on SCCEDs

and bullous keratopathy; treatment of the other causes of nonhealing erosions is covered in other chapters in this section (and in Section XII on Evolve).

TREATMENT

Spontaneous Chronic Corneal Epithelial Defects

Many treatments have been proposed for patients with SCCEDs, which suggests that no one therapy is ideal. Client education at the onset of treatment is crucial in the successful management of this problem. Clients must understand that multiple treatments may be required and that electing no treatment could result in persistence of the defect and relegate their pet to months of discomfort.

Overall it is important to remember that SCCEDs are by definition nonseptic; therefore frequent application of topical antibiotics is unnecessary. Topical antibiotics should be administered for prophylaxis just two or three times daily. Appropriate broad-spectrum choices for antibiotic therapy are neomycin/polymyxin/gramicidin or gentamicin. Changing antibiotics will not improve healing unless the animal is experiencing a toxic reaction to the antibiotic. Topically applied antibiotics also may delay wound healing. Oral antibiotics typically do not reach the avascular cornea in therapeutic concentrations and are not recommended.

Medical Therapy

A large number of medical therapies for SCCEDs have been suggested. These include drugs such as polysulfated glycosaminoglycans and aprotinin, which decrease proteolytic activity. Doxycycline has been suggested for human use because this drug inhibits matrix metalloproteinases (proteolytic enzymes that degrade components of the basement membrane). However, canine studies suggest that matrix metalloproteinases are not elevated in SCCEDs; therefore doxycycline or other factors that decrease proteolytic activity may not be indicated. Growth factors such as epidermal growth factor and substance P (a neuropeptide found in sensory nerves) have also been used to treat SCCEDs with some success. An antibiotic/chondroitin sulfate combination demonstrated some efficacy, but therapy had to be continued for at least 4 weeks—longer than most other therapies for SCCEDs.

The evidence recommending any topical treatment for canine SCCED is limited. Most canine studies of topical medications have involved small groups of dogs in non-randomized and uncontrolled clinical trials. Furthermore, most medical treatment studies are isolated, with no further substantiation. Accordingly, interpretation of results is difficult, particularly since most studies included epithelial débridement (see following paragraph), which makes differentiating between resolution caused by drug administration versus epithelial débridement very difficult. Furthermore, many topical therapies have limited to no availability, or the treatment is cost prohibitive, making their widespread use impractical in the private practice setting.

Débridement/Surgical Therapy

Morphologic studies have revealed that distinctive stromal alterations occur in dogs with SCCEDs but not in those undergoing repeated mechanical epithelial débridement, suggesting that stromal alterations likely are intimately involved in the pathophysiology of SCCEDs. Accordingly, treatments that alter the stroma are more successful than medical therapies. A number of procedures may be beneficial, and these are generally performed in the order described in the following paragraphs, with 10 to 14 days separating procedures. Following any of these procedures, the application of a contact lens or creation of a third eyelid flap may improve healing times while also appearing to make patients more comfortable. Epithelial débridement and anterior stromal puncture/grid keratotomy are less invasive and can be repeated multiple times until healing is obtained. Superficial keratectomy is more advanced and can be performed only once. Generally the least invasive approach is taken initially. However, one of the more invasive procedures is not necessarily contraindicated at the first visit, particularly in patients with a protracted history of ulceration.

Epithelial débridement is the least invasive and probably most common treatment for SCCEDs. It is easily performed in conscious patients after application of a topical anesthetic such as proparacaine. Multiple dry, sterile, cotton-tipped applicators are used to gently remove the loose epithelium, starting in the center of the erosion and working toward the corneoscleral limbus in radial motions. The normal attachments of the epithelium to the underlying corneal stroma are extremely strong, and normal corneal epithelium cannot be removed with a cotton-tipped applicator. Therefore débridement should continue until all loose epithelium is removed, which often results in a much larger area of epithelium being removed than originally demonstrated by fluorescein staining. Combining results from various studies suggests a success rate with this technique of approximately 50%.

A more invasive technique involves making either small, superficial punctures or linear scratches in the corneal stroma. Various names and descriptions have been applied to these procedures, including anterior stromal puncture, punctate keratotomy, multiple punctate keratotomy, multifocal superficial punctate keratotomy, and grid keratotomy. It is believed that these punctures create areas for the epithelial cells to penetrate the stromal abnormalities found in patients with SCCEDs. This is supported by the observations of ophthalmologists who developed anterior stromal puncture to treat humans. They noted that recurrent erosions in humans occurred after superficial injury but never after deep injury to the cornea. In my experience anterior stromal puncture results in less scarring and is used preferentially, but these procedures work through the same mechanism and can be grouped together.

To perform an anterior stromal puncture or grid keratotomy, hemostats are used to clamp a 25-gauge needle so that the tip of the needle is barely exposed. This technique allows precise control of the needle and prevents its penetration too far into the corneal stroma. Commercially available anterior stromal puncture needles, with a small curve in the tip of the needle, may also be used (Stromal

puncture needle No. 3800, Surgical Specialties Corp.). Before performing the puncture, topical anesthesia is applied, and the loose epithelium is débrided to expose the full extent of the erosion as described previously. Multiple small punctures are then made approximately 0.5 to 1 mm apart across the surface of the defect and into the surrounding, normal-appearing cornea. A grid keratotomy is performed by making lines in a cross-hatched pattern completely across the affected cornea, from normal cornea across the epithelial defect to normal cornea. Combining results from multiple studies suggests a success rate of approximately 80%.

The most invasive procedure for the treatment of SCCEDs is superficial keratectomy. In this technique the affected area is outlined with a corneal trephine, and the abnormal cornea is superficially undermined and removed. Generally the anterior 150 μ m to 200 μ m of superficial stroma is removed in this procedure. Care must be taken to débride the loose epithelium to delineate the lesion and ensure that the entire affected area of the cornea is removed. After removal of the abnormal tissue, a contact lens or third eyelid flap can be placed. Unlike the two procedures described previously, superficial keratectomy requires general anesthesia and usually neuromuscular blockade, an operating microscope, and precise microsurgical technique. This procedure should be done by a veterinary ophthalmologist. It probably works by removing the entire area of abnormal superficial stroma, thereby allowing epithelial adhesion. Results from multiple studies suggest a success rate of 100% within 2 to 3 weeks. Although this technique has the highest success rate, it is not often recommended as initial therapy because of the need for referral, the risks associated with general anesthesia, the increased cost, and the increased probability of corneal scarring.

Bullous Keratopathy

Bullous keratopathy is characterized by corneal edema with the formation of large subepithelial bullae. These expose corneal nerves and cause significant pain when they rupture. Medical therapy of bullous keratopathy is often unrewarding. Topical hypertonic agents increase tear film tonicity, which draws excess fluid from the epithelium. As such they may palliate epithelial edema; however, they have no significant effect on stromal edema. The most commonly used ophthalmic hypertonic agent is 5% sodium chloride solution or ointment. Ointment used four times daily appears to be more effective and better tolerated in canine patients with bullous keratopathy. If erosions are present, topical broad-spectrum antibiotics should be used as described for SCCEDs. Contact lenses may relieve pain and discomfort and protect corneal epithelium from mechanical trauma. Contact lenses can be left in place for 2 weeks, and an Elizabethan collar should be placed to facilitate retention.

Surgical therapy provides the most definitive treatment of bullous keratopathy. Goals of therapy are pain relief and visual recovery, if possible. In veterinary medicine pain relief is often the only easily obtainable goal. Thermal cautery is an easy and practical surgical option

for painful bullous keratopathy but usually requires referral. In this process the anterior stroma is denatured by heat. This destroys the abnormal epithelial basement membrane while altering the anterior stroma. Thermal cautery creates a light subepithelial scar that is a barrier to fluid flux. This barrier prevents the formation of bulla and allows the epithelium to reattach. Excessive scar formation often results in decreased vision, but the animals are usually comfortable. If scar formation is minimal, vision can be retained, but owners should be warned that vision might decrease after surgery.

The procedure is performed with the animal under general anesthesia (and sometimes with neuromuscular blockade), using disposable handheld thermal cautery to make small, superficial burns across the affected area after epithelial débridement. A blunt-tipped diathermy probe on its lowest setting may also be used. Several hundred burns may have to be placed. In cases of corneal endothelial degeneration or dystrophy, corneal edema is typically progressive; thus the entire cornea often must be treated to prevent recurrences or new lesions. After surgery a contact lens should be placed, and broad-spectrum topical antibiotics used. Mydriatic agents should be used if the patient appears to be in pain, provided that tear production is normal. After the cornea is epithelialized, topical corticosteroids may be used to decrease scar formation. Skill with microsurgical techniques and a familiarity with working under magnification (preferentially an operating microscope) are required; therefore referral to an ophthalmologist is recommended.

Anterior stromal puncture has been advocated in humans with bullous keratopathy as a means of improving their comfort while awaiting penetrating keratoplasty, which is also the definitive treatment for humans. The punctures penetrate the abnormal basement membrane and anterior stroma, allowing focal epithelial adhesions to occur. One advantage of this procedure is that usually it can be performed in conscious animals using topical anesthesia, which can be an important consideration in elderly patients with endothelial degeneration. Anterior stromal puncture also causes less scarring than thermal cautery but may not be as effective long term since it does not significantly alter the anterior stroma.

Finally, a thin conjunctival flap may also be placed over the cornea in cases of painful bullous keratopathy. Generally thermal cautery is preferred since there is a better chance of retaining vision; however, a thin, partial conjunctival flap may result in decreased edema and retention of vision. This procedure usually requires referral to a veterinary ophthalmologist.

CHAPTER 262

Anterior Uveitis in Dogs and Cats

CYNTHIA C. POWELL, *Fort Collins, Colorado*

Uveitis is a general term describing inflammation of any portion of the uveal tract. Anterior uveitis (inflammation of the iris and ciliary body) and chorioretinitis (inflammation of the choroid and the adjacent retina) are common in cats and dogs. Although uncommon, intermediate uveitis (inflammation centered in the pars plana or junctional area between the posterior-most ciliary body and anterior-most choroid) also occurs. Uveitis results from any injury disrupting the blood-ocular barriers. However, the eye has limited responses to injury; thus uveitis often presents with a similar appearance, regardless of underlying cause. This situation often prompts additional diagnostic steps.

Some of the more common causes of uveitis include trauma, infection, immune-mediated diseases, and neoplasia. After the cause of uveitis is determined, the goals of therapy are to remove the inciting cause, stop inflammation, control pain, and prevent or treat secondary complications, including glaucoma. This main focus of this chapter is anterior uveitis.

ANATOMY AND PHYSIOLOGY

As in other tissues, intraocular inflammation is initiated by local tissue injury (e.g., trauma, infectious agent, antigenic challenge). Damaged tissue and microorganisms release tissue factors that cause vasodilation and changes in vascular permeability, leading to disruption of the blood-ocular barrier. Inflammatory mediators are also released by damaged tissue and cause leukocyte activation and migration. The globe has no lymphatic drainage; thus antigens from degraded organisms are transported via the bloodstream to the spleen or other lymphoid tissue, where they activate antigen-specific T and B lymphocytes.

Immunocompetent T and B lymphocytes then migrate back to the eye and reside in the uveal tract. Elimination of the inciting antigen and production of inhibitory cytokines by T and B lymphocytes help to turn off the ocular immune response. Chronic inflammation results if the inciting antigen cannot be removed completely or the immune response is not appropriately damped.

CLINICAL MANIFESTATIONS

The clinical signs of anterior uveitis in the dog and cat vary, depending on location, duration, and severity of inflammation. Hyperemia or “injection” of conjunctival and episcleral vessels and leakage of intravascular constituents into the anterior chamber are hallmarks of anterior uveitis. Increased protein concentration in the aqueous humor results from disruption of the blood-ocular barrier and is visible to the examiner as *aqueous flare*. Aqueous flare sometimes can be subtle and difficult to detect (see Chapter 248). However, once there is notable exudation of protein (especially if accompanied by white or red blood cells), the anterior chamber appears more obviously cloudy. When corneal edema is present, it also contributes to cloudiness. Inflammatory cells in the aqueous humor may be deposited on the corneal endothelium as keratic precipitates (KPs) (Fig. 262-1). Normal convection currents within the aqueous humor cause KPs to be located primarily on the ventral half of the cornea. KPs vary in size and may persist for some time after resolution of uveitis.

The iris undergoes many changes in patients with anterior uveitis. Prostaglandin release results in miosis by directly inciting spasm of the iris sphincter muscle. However, miosis may be very mild or absent when uveitis

Fig. 262-1 **A**, Feline eye with anterior uveitis of unknown origin. Many large keratic precipitates (KPs) can be seen primarily located on the ventral half of the cornea. KPs are pathognomonic for anterior uveitis. This photograph was taken using retroillumination from the tapetal reflection, causing the KPs to appear dark. **B**, Canine eye with anterior uveitis of unknown origin. Numerous small KPs cover the ventral and central cornea, making it difficult to see into the anterior chamber. There is also marked episcleral injection and some corneal neovascularization, which, although highly suggestive of anterior uveitis, are not pathognomonic.

is chronic. Subtle sphincter muscle spasm is not evident as miosis but results in an eye that is unresponsive or poorly responsive to tropicamide or other mydriatics. Inflammation also causes ciliary muscle spasm, a major contributor to ocular pain. Iritis, manifested by iris vasodilation and increased iris vessel permeability, often causes a subtle-to-pronounced iris color change. On close examination dilated iris vessels may be obvious (Fig. 262-2), and the iris may appear swollen or “muddy” with loss in tissue architecture or detail. As anterior uveitis becomes more chronic, the iris may form posterior synechia (adhesions to the anterior lens capsule), giving the pupil an irregular shape (*dyscoria*) and impairing its ability to respond to light or dilating agents (Fig. 262-3). If posterior synechia involve the entire pupil margin, aqueous humor cannot move from the posterior chamber (between the iris and lens) to the anterior chamber. In this situation aqueous humor accumulates behind the iris, causing it to billow forward, a condition known as *iris bombé* (see Fig. 262-3). Peripheral anterior synechia (adhesions of the iris root to the cornea) can also form as a result of iris bombé or iris swelling and inflammation.

Intraocular pressure (IOP) can be quite variable in patients with anterior uveitis. Generally aqueous humor formation is impaired, and IOP is lowered when the ciliary body is inflamed. However, anterior uveitis can predispose to development of secondary glaucoma via a number of mechanisms. Inflammatory cells, iris swelling, and peripheral anterior synechia can impair aqueous outflow directly, contributing to the development of

secondary glaucoma. In addition, iris bombé prohibits access of the aqueous humor to the anterior chamber and filtration angle, and the forward bowing of the iris obstructs the angle itself. Therefore IOP typically is low in acute uveitis. However, as aqueous humor outflow is impaired by any of these mechanisms, IOP begins to move into the normal range and continues to increase as secondary glaucoma develops.

Pars planitis (or *intermediate uveitis*) causes exudation of inflammatory cells from the pars plana behind the ciliary processes and just anterior to the peripheral retina. These white blood cells accumulate in the peripheral anterior vitreous as white, punctate infiltrates (Fig. 262-4). This so-called *snow-banking* usually requires pupil dilation for detection.

Posterior uveitis is inflammation of the posterior uvea or choroid. Because of their close apposition, retinal inflammation often accompanies inflammation of the choroid; together the syndrome is known as *chorioretinitis*. As with anterior uveitis, the signs of chorioretinitis are related to breakdown of the blood-ocular barrier. In the posterior segment the barrier is contributed to by the retinal blood vessels and the retinal pigment epithelium. Increased permeability of this barrier allows components of the blood to enter the subretinal space and retina. Clinically

Fig. 262-2 Feline eye with anterior uveitis of unknown origin. The iris is swollen, and the iris vasculature injected. A fibrinous clot can also be seen in the ventral anterior chamber.

Fig. 262-3 Canine eye with chronic anterior uveitis secondary to uveodermatologic syndrome. The cornea has peripheral neovascularization. The pupil has an irregular shape (*dyscoria*), there is melanotic debris on the anterior lens capsule (both caused by posterior synechia), and there is iris bombé.

Fig. 262-4 Feline eye with pars planitis or intermediate uveitis. Cellular debris can be seen collecting in a generally cloudy vitreous behind the lens, just inside the dilated pupil. The vitreous cloudiness is caused by inflammatory cells accumulating around the ciliary body (*snow-banking*) and is evidence of pars planitis.

retinal and subretinal edema, exudation, and hemorrhage can be detected (see Chapter 264). Since the retina and subretinal space overlie the tapetum, tapetal reflectivity is diminished or obscured by areas of active chorioretinitis (Fig. 262-5). Severe chorioretinitis can lead to partial or complete retinal detachment, decreased vision, and blindness. Inflammation of both the anterior and posterior uvea is termed *panuveitis*.

DIAGNOSIS

Common causes of anterior uveitis in the dog and cat are summarized in Box 262-1. Anterior uveitis is often associated with systemic diseases, some of which are quite serious. Causes of anterior uveitis unrelated to systemic disease, such as blunt or sharp trauma to the globe, keratitis, and lens-induced uveitis, are often diagnosed simply by obtaining a good history and performing a complete ocular examination. If a systemic disease is suspected as

the cause of uveitis, a general physical examination and assessment of a complete blood count, serum chemistry panel, and urinalysis are indicated. The need for imaging studies, ocular ultrasound, and serologic or microbiologic assays is based on results of the physical examination, initial laboratory tests, and clinical suspicion. Diagnosing the cause of uveitis may require examination of either aqueous or vitreous humor. These two ocular fluids can be assessed by cytology, culture and sensitivity, polymerase chain reaction (PCR), and determination of antibody content.

Anterior Chamber Paracentesis

General anesthesia is required for this procedure. Supplies needed to perform paracentesis include a 25- or 27- gauge needle on a 1- or 3-ml syringe, small rat-toothed forceps, adequate lighting, and magnification. The bulbar conjunctiva and cornea are gently flushed with a 1:20 solution of povidone-iodine diluted in sterile saline. (Do *not* use povidone-iodine or Betadine scrub!) Grasp the globe at the limbus with forceps. The dorsolateral limbus is usually the easiest to access. The needle should enter the eye adjacent to the forceps at the limbus and parallel to the iris plane (Fig. 262-6). Care should be taken to keep the needle bevel up and the tip away from the iris and lens. Up to 0.3 ml of aqueous humor can usually be removed slowly without collapsing the anterior chamber. After withdrawing the needle, gentle pressure is applied to the centesis site using a moistened cotton swab. Samples of aqueous humor can be dropped directly onto a swab for culture and sensitivity or stored in a sterile container (such as a red top) for antigen or antibody determination. Cytology is best done on samples stored in a 1.5-ml draw ethylenediaminetetraacetic acid-containing tube, concentrated by centrifugation, and stained with Diff-Quik or Wright's stain. PCR may require a special transport medium. The performing laboratory should be contacted for appropriate handling procedures. Mild hyphema is the most common complication of aqueous humor paracentesis. Serious complications are rare if care is taken to avoid contact with the iris or lens.

Vitreous Paracentesis

Vitreous paracentesis is only considered when other methods of diagnosis have been unrewarding or if a large vitreous mass or subretinal exudate is found during ophthalmoscopic or ultrasonographic examination of the

Fig. 262-6 Anterior chamber centesis. The needle enters the eye at the limbus on a plane parallel with the iris and with bevel up to avoid aspiration of the iris into the needle tip.

globe. Because of the potential for severe intraocular hemorrhage, retinal tears, retinal detachment, and blindness, this should be performed by trained clinicians or reserved for blind or nearly blind eyes. In patients with a blind and painful eye, enucleation is more likely to yield a diagnosis and is also therapeutic. General anesthesia is required for vitreous paracentesis. Before aspiration, the bulbar conjunctiva is cleaned gently with 1:20 povidone-iodine and sterile saline solution to remove all mucus and debris. The dorsolateral globe is grasped 6 to 7 mm behind the limbus with small, toothed forceps. Vitreous is viscous and can be difficult to aspirate; thus a 3-ml syringe is needed for adequate suction. Aspiration through a 25-gauge needle can be attempted first, but a 22-gauge needle often is needed to obtain a sample sufficient for analysis. The needle should be aimed toward the center of the globe and should be introduced into the eye 7 to 9 mm posterior to the limbus, adjacent to the forceps for maximal stabilization (Fig. 262-7). If a mass is present, the needle can be guided via ultrasound into the mass for aspiration. If the ocular media are clear, the needle can be guided by direct visualization, using indirect ophthalmoscopy. Care should be taken not to advance the needle across the globe into the retina and choroid opposite the site of entry. Slightly altering the

Fig. 262-7 Diagram of vitreous paracentesis. The needle enters the eye 7 to 9 mm behind the dorsolateral limbus and is directed toward the center of the vitreous.

needle position may help if there is difficulty in aspirating fluid. If bacterial endophthalmitis is suspected and a vitreous injection of antibiotic is planned, the syringe should be removed from the needle hub, leaving the needle in place for injection. Vitreous samples should be handled in the same manner as aqueous humor samples for culture, cytology, and PCR assays.

CAUSES

Infectious causes of anterior uveitis are common in dogs and cats. Outdoor cats with anterior uveitis should be tested routinely for *Toxoplasma gondii*, feline leukemia virus (FeLV), and feline immunodeficiency virus (FIV); and cats reared in a cattery or less than 2 years of age should be screened routinely for coronavirus. Although the appearance of uveitis cannot be used to distinguish one cause from another, large KPs (see Fig. 262-1) are more likely to be associated with diseases causing granulomatous inflammation such as feline infectious peritonitis (FIP) or toxoplasmosis; and pars planitis is more likely to be associated with FIV or toxoplasmosis. Ocular lesions of anterior and/or posterior uveitis are most often seen with the nonexudative or “dry” form of FIP. Although a definitive diagnosis of ocular toxoplasmosis is difficult to make and confirm, treatment with an anti-*Toxoplasma* drug is justified when other causes of uveitis have been ruled out and there is serologic evidence of recent or active infection, intraocular *T. gondii* antibody production (particularly immunoglobulin M), or presence of *T. gondii* deoxyribonucleic acid in aqueous humor. Ocular disease does not occur with FeLV infection except by its association with the development of lymphosarcoma or by immune suppression and increased susceptibility to other infectious diseases such as *T. gondii* and systemic mycoses. Clinically cats infected with FIV may develop anterior uveitis, pars planitis, or glaucoma. Screening and treatment for *Bartonella* spp. should be done in cats when other causes of uveitis have been ruled out. Many healthy cats have positive serologic titers for *Bartonella* spp. Cats with uveitis were actually less likely to have a positive *Bartonella* titer.

Ocular signs of systemic mycoses occur in both dogs and cats. Systemic mycoses primarily cause granulomatous chorioretinitis. Anterior uveitis is usually secondary to

severe posterior segment infection and inflammation. Blastomycosis and histoplasmosis are found most often in the southern and midwestern United States, and coccidiomycosis in the southwestern United States. Cryptococcosis is found throughout the United States and is the most common mycotic organism to infect cats. *Prototheca* spp. are soil algae that infrequently cause systemic disease in dogs and can cause ocular signs of granulomatous chorioretinitis and anterior uveitis, which are similar to those of systemic mycoses.

Typically, depending on their location and travel history, dogs with anterior uveitis are screened for systemic mycoses, rickettsial diseases, brucellosis, and borreliosis. Rocky Mountain spotted fever (*Rickettsia rickettsii*), and ehrlichiosis (*Ehrlichia* spp.) are found throughout most of the United States but especially in the southeast and southwest. Ocular signs of rickettsial disease are common and can include both anterior and posterior segment inflammation and ocular hemorrhage, including hyphema and retinal hemorrhage. Brucellosis in dogs generally manifests as reproductive disease; but the organism can localize in bone, spleen, kidney, meninges, or the uveal tract. Clinical signs related to ocular involvement include anterior and posterior uveitis, keratitis, and optic neuritis. Lyme borreliosis is most prominent in the northeastern and midwestern United States. Although uncommon, ocular signs of anterior uveitis and chorioretinitis have been reported in dogs with borreliosis.

In spite of aggressive diagnostic testing, a specific cause will not be found in many patients with uveitis, and the cause is often considered to be immune-mediated. In these patients infectious causes still must be considered and ruled out before treatment because therapy requires systemic immune suppression. There are some immune-mediated forms of uveitis in which the offending antigen is recognized. For example, leakage of lens proteins as occurs with mature-to-hypermature cataracts or with traumatic lens capsule rupture elicits an autoimmune response and lens-induced uveitis. Likewise, anterior and posterior uveitis accompanied by poliosis and vitiligo in dogs is highly suggestive of uveodermatologic syndrome, an immune-mediated disease targeting melanin or melanocytes (see Fig. 262-3; Fig. 262-8). However, ocular signs often occur before dermatologic signs, making the diagnosis more difficult. Recently uveitis associated with iris and ciliary body cysts has also been recognized. Golden retrievers are affected most frequently. The hallmark of this disease is the appearance of pigment on the anterior lens capsule associated with clinical signs of chronic anterior uveitis (Fig. 262-9). The disease is presumed to be inherited and immune mediated. The prognosis is guarded, and many patients lose vision as a result of secondary glaucoma despite treatment.

Lymphosarcoma is the most common neoplasm associated with anterior uveitis in both dogs and cats, although many other tumor types have been reported. Lymphosarcoma can appear as a masslike lesion, or it can diffusely infiltrate the iris. When diffuse, lymphosarcoma appears very similar to other causes of anterior uveitis.

Fig. 262-8 Dog with uveodermatologic syndrome, which is a severe cause of immune-mediated panuveitis in which melanocytes are targeted. There is pigment loss in the skin (vitiligo) and hair (poliosis), especially around the eyes and nose.

Fig. 262-9 Golden retriever with pigmentary uveitis. A large cyst can be seen in the ventral anterior chamber. Dorsolaterally there is a blood-filled ciliary body cyst adjacent to pigment streaks on the anterior lens capsule.

GENERAL PRINCIPLES OF TREATMENT FOR UVEITIS

The primary treatment goals for uveitis are to stop inflammation, prevent or control the ocular complications of uveitis, and relieve pain. Specific and nonspecific therapies are involved in treatment of uveitis. Specific therapies are used for infectious agents (e.g., bacteria, protozoa, fungi, neoplasia) or other contributors to inflammation (e.g., foreign body, corneal ulcer, luxated lens) identified through the examination and diagnostic evaluation. Nonspecific therapy includes decreasing the ocular inflammatory response with antiinflammatory drugs, mydriasis to prevent synechia formation, and cycloplegia to decrease pain. Ocular hypotensive therapy is also instituted when there is evidence of secondary glaucoma resulting from decreased aqueous humor outflow (see Chapter 263).

Nonspecific Therapy for Uveitis

Antiinflammatory therapy is critical in the treatment of uveitis, regardless of the cause. Failure to control inflammation can lead to anterior and posterior synechia, glaucoma, cataracts, retinal detachment, vitreous degeneration, optic nerve atrophy, and retinal degeneration. Glucocorticoids and nonsteroidal antiinflammatory drugs (NSAIDs) are commonly used to control inflammation. Glucocorticoids can be administered topically, subconjunctivally, or systemically. Anterior uveitis is usually treated topically a minimum of every 4 to 6 hours and as frequently as every 2 hours, depending on the severity of inflammation. Aggressive treatment is continued until the inflammation is controlled; then the frequency of administration should be slowly tapered. If inflammation is not controlled or if frequent treatments are not possible, supplementation with oral glucocorticoids should be considered. Topical preparations with the best potency and corneal penetration are prednisolone acetate suspension (1%) and dexamethasone solution (0.1%) or ointment (0.05%). Topical glucocorticoids are contraindicated in the presence of corneal ulceration because they inhibit wound healing and augment collagenase activity in the cornea. Systemic administration of glucocorticoids has minimal corneal effects unless the cornea is heavily vascularized; therefore this therapy can be given if both corneal ulceration and anterior uveitis are present.

Ocular release of prostaglandins can cause disruption of the blood-ocular barrier and uveitis. NSAIDs decrease inflammation by inhibiting cyclooxygenase, resulting in decreased production of prostaglandins. Unlike glucocorticoids, NSAIDs do not inhibit the lipoxigenase inflammatory pathway. Therefore glucocorticoids tend to control uveitis more potently, and NSAIDs should be considered primarily when glucocorticoids are contraindicated. Frequently used topical ophthalmic NSAIDs include diclofenac 0.1%, flurbiprofen 0.03%, suprofen 1%, and ketorolac 0.5%. Ocular hemorrhage caused by inhibited platelet aggregation can be a potential complication of their use. Topical NSAIDs may complicate bacterial corneal infections and are not recommended when corneal infection is present.

Systemically administered drugs are necessary to treat posterior uveitis because therapeutic concentrations cannot be attained in the retina and choroid with topical drugs. Because glucocorticoids suppress the immune response, they should be used systemically with caution (if at all) when an infectious agent is suspected. If used during infection, concurrent treatment with an effective antimicrobial is essential. Glucocorticoid preparations, dosages, and routes of administration can be found in Table 262-1. Systemic NSAIDs can also be used in dogs and cats, with careful attention to dose, frequency of administration, and possible side effects. Use of systemic NSAIDs in cats has been associated with potentially serious side effects, including bone marrow suppression, gastrointestinal ulceration, hemorrhage, vomiting, and diarrhea. Gastrointestinal side effects, including melena, vomiting, diarrhea, hematemesis, and gastrointestinal ulceration, have been reported in dogs.

Table 262-1

Drugs Commonly Used for the Treatment of Uveitis in Cats and Dogs

Drug	Route of Administration Treatment Regimen
Topical Glucocorticoid	
Prednisolone acetate 1% (suspension)	q1-12h
Dexamethasone sodium phosphate 0.1% (solution), 0.05% (ointment)	q1-12h
Topical NSAID	
Diclofenac 0.1% (solution)	q6-12h
Flurbiprofen 0.03% (solution)	q6-12h
Suprofen 1% (solution)	q6-12h
Ketorolac 0.5% (solution)	q6-12h
Topical Mydriatic/Cycloplegic (parasympatholytic)	
Atropine sulfate 0.5%, 1% (solution and ointment)	q8-24h
Tropicamide 0.5%, 1% (solution)	q6-12h
Topical Mydriatic (sympathomimetic)	
Phenylephrine hydrochloride 2.5%, 10% (solution)	In conjunction with parasympatholytic
Systemic Glucocorticoid	
Prednisolone 5-mg tablet or Prednisone 5-mg, 20-mg tablet	0.5 to 2.2 mg/kg q12-24h (Higher dosages for initial therapy of severe inflammation)
Systemic NSAID	
Acetylsalicylic acid 80-mg tablet	Cat: 10-20 mg/kg q48-72h PO Dog: 10 mg/kg q12h PO
Ketoprofen 12.5-mg tablet	Cat: ≤2 mg/kg PO once, ≤1 mg/kg q24h Dog: ≤2 mg/kg PO once, ≤1 mg/kg q24h
Meloxicam 1.5 mg/ml	Cat: 0.2 mg/kg PO initially, followed by 0.1 mg/kg PO (in food) q24h × 2 days, then 0.025 mg/kg two to three times a week Dog: 0.2 mg/kg PO initially followed by 0.1 mg/kg PO (in food) once daily Dog: 2.2 mg/kg q12-24h
Carprofen 25-mg, 75-mg, 100-mg tablet	Dog: 1-2 mg/kg PO q24h or 3-4 mg/kg PO q24h (do not exceed 7 days' therapy at this dose)
Deracoxib 25-mg, 100-mg tablet	
Subconjunctival Glucocorticoid	
Methylprednisolone acetate	4 mg/eye
Betamethasone	0.75 mg/eye
Triamcinolone	4 mg/eye

NSAID, Nonsteroidal antiinflammatory; PO, orally.

Subconjunctivally administered glucocorticoids have been used to supplement topical or systemic therapy in cases of severe ocular inflammation or in patients in which frequent topical treatment is not possible. Commonly used subconjunctival preparations are long acting and give a constant source of drug release for a 2- to 4-week period. A disadvantage to their use is the inability to withdraw the medication if complications such as corneal ulceration arise. Drugs injected subconjunctivally enter the eye through the sclera and, following leakage back out the injection site, through the cornea. Therefore subconjunctival glucocorticoids are contraindicated with corneal ulceration and should be used with extreme caution in dogs prone to development of corneal ulcers, such as brachycephalic breeds. Topical and subconjunctival glucocorticoid use may also result in reactivation of feline herpesvirus-1 (FHV-1) in carrier cats with previous episodes of viral keratitis or conjunctivitis. Therefore it is best not to administer subconjunctival glucocorticoid to cats suspected to have recurrent FHV-1-related ocular disease.

Cycloplegic drugs relieve pain associated with anterior uveitis by relaxing the ciliary body muscle spasm. These agents also cause mydriasis, which can prevent or break down posterior synechia by decreasing iris-lens contact. Cycloplegia and mydriasis can be accomplished by using a parasympatholytic agent. Topical 1% atropine sulfate ointment is used most commonly because the ocular solution is more likely to reach the mouth via the nasolacrimal duct and cause profuse salivation because of its bitter taste, especially in cats. The duration and frequency of application depend on the severity of ocular inflammation. Very mild inflammation is usually treated only once daily, severe inflammation may require treatment up to three to four times daily to maintain iris dilation. Because parasympatholytic agents can decrease tear production, they are best applied "to effect" (i.e., in sufficiently frequently to maintain pupil dilation). The addition of a sympathomimetic may help to achieve mydriasis when synechia have already formed but does not provide the analgesic effect associated with cycloplegia.

PROGNOSIS

The fate of an eye with anterior uveitis rests on a number of factors. Inflammation that can be brought under control very quickly may not leave any evidence of previous uveitis. Consequences of long-standing inflammation can include impaired vision, blindness, or marked ocular pain. Iris inflammation and swelling, inflammatory cells and debris, and iris bombé secondary to posterior synechia all can contribute to obstruction of the iridocorneal angle, resulting in secondary glaucoma. Chronic uveitis can also stimulate the growth of a fibrovascular membrane across the iris, pupil, and iridocorneal angle, which can lead to glaucoma. Secondary glaucoma is very common with anterior uveitis; thus IOP measurements are an integral part of management. Other sequelae to chronic anterior uveitis are development of cataract and retinal inflammation and degeneration. Whether vision-threatening changes occur depends on the severity and chronicity of the inflammation, as well as the cause, timeliness, and appropriateness of therapy and the response to it.

CHAPTER 263

Feline Glaucoma

PAUL E. MILLER, *Madison, Wisconsin*

Glaucoma is a group of disorders united by a common theme in which intraocular pressure (IOP) is too high to permit the optic nerve, and perhaps the retina, to function normally. Ultimately this results in partial or complete loss of vision. The IOP threshold at which vision loss occurs varies considerably from individual to individual, but in general most cats do not tolerate IOP in excess of 25 to 27 mm Hg for very long, and in some animals visual impairment occurs well before this level. The chance of vision loss is directly related to both the magnitude and duration of the increased IOP. For example, a gradual increase in IOP of a few millimeters of mercury may be tolerated for months without overt visual impairment, whereas sudden marked rises (to 50 to 60 mm Hg) often result in irreversible blindness in a

matter of hours to days. In some animals vision may continue to be lost because of glaucoma even after IOP has returned to normal.

ANATOMY AND PHYSIOLOGY

A stable IOP requires that aqueous humor production match aqueous humor outflow. Thirty percent of aqueous humor is produced by passive diffusion; the remaining 70% is made by several active, energy-dependent processes, one of which involves the enzyme carbonic anhydrase. The rate of passive diffusion varies inversely with IOP, thereby creating a mechanism for balancing production and outflow. However, active secretion continues at roughly the same rate even if IOP is elevated

since it is the major source of nutrition for the eye and the only alternative of the eye is to “starve.” Aqueous humor exits the eye via either the conventional pathway (97% in cats) or the uveoscleral pathway (3% in cats). In conventional outflow aqueous humor, which is formed at the tips of the ciliary processes, enters the posterior chamber between the iris and lens, passes through the pupil into the anterior chamber, flows between the strands of the pectinate ligament of the iridocorneal (drainage) angle into the trabecular meshwork, and then drains into the episcleral veins and the systemic circulation. In the uveoscleral pathway aqueous humor percolates through the ciliary body interstitium and ultimately “leaks” through the sclera into the orbit, where it is picked up by orbital lymphatic vessels.

GLAUCOMA CLASSIFICATION

Glaucoma is almost invariably caused by impairments in the aqueous humor outflow pathways that exceed the compensatory abilities of the passive production system. One of the most useful ways of classifying glaucoma, then, is by the location of the impediment (block) to outflow (Box 263–1). Cats with long-standing glaucoma often have multiple obstructions to outflow, explaining in part the difficulty in treating advanced glaucoma in this species. However, understanding the location of these blocks forms the basis for creating a rationale treatment plan that is tailored for each individual.

Other ways of classifying glaucoma include whether the inciting cause is primary or secondary, whether the iridocorneal (drainage) angle is open or closed, and by disease duration. *Primary glaucoma* refers to glaucoma that has no consistent, obvious association with another ocular or systemic disorder. Although uncommon in cats, primary glaucoma is typically bilateral, has a strong breed association, is probably genetic, and may or may not be congenital in onset. *Secondary glaucoma* is associated with another ocular or systemic disorder (e.g., chronic uveitis, intraocular neoplasia) that alters aqueous humor dynamics. Secondary glaucoma may be unilateral or bilateral, may or may not be inherited, and typically is seen in adult cats. These two major categories are further subdivided by whether the drainage angle is *open* or *closed*. Although the latter distinction is best made with a specialized gonioscope, it is possible to see a portion of the feline drainage angle with an indirect ophthalmoscope and condensing lens held at an extreme angle to the eye so that the iridocorneal junction is the focal point of the lens instead of the retina.

EPIDEMIOLOGY

According to data collected by the Veterinary Medical Data Base, 1 in 367 (0.3%) of cats presenting to University Teaching Hospitals had a diagnosis of glaucoma. However, this referral population estimate may be low since a study that prospectively screened cats 7 years of age or older in a feline exclusive private practice found that 0.9% of cats (1 in 108) had abnormally high IOP (Kroll et al., 2001). In both of these populations and in several other case series of cats with glaucoma, glaucoma was secondary 95% to

Box 263-1

Classification of Glaucoma by Location of the Barrier to Aqueous Humor Outflow

1. Posttrabecular meshwork forms
 - a. Episcleral vein obstructions
 - b. Scleral outlet channel obstructions
 - c. Angular aqueous plexus obstructions
2. Trabecular meshwork obstructions
 - a. Primary open-angle glaucoma
 - (1) Adult-onset
 - (2) Primary juvenile-onset open-angle glaucoma
 - b. Secondary obstructions of a conformationally open angle
 - (1) Pretrabecular forms: preiridal fibrovascular membranes
 - (2) Trabecular forms: material within the meshwork
 - Vitreous
 - Plasma proteins
 - Neoplastic cells
 - Red blood cells (intact or ghost)
 - Pigment
 - Epithelial down-growth
3. Block at the level of the angle
 - a. Primary angle-closure glaucoma
 - b. Secondary angle-closure glaucomas
 - (1) Anterior “pulling” (e.g., peripheral anterior synechia)
 - (2) Posterior “pushing” ± pupillary block
4. Block at the level of the iris (pupillary block)
 - a. Relative pupillary block caused by iris-lens apposition
 - b. Posterior synechia/iris bombé (absolute block)
 - c. Lens within pupil aperture: luxations, intumescent lens
 - d. Vitreous within pupil aperture
5. Block at the level of the ciliary body
 - a. Plateau iris: large or anteriorly rotated ciliary processes
 - b. Iris-ciliary body cysts
6. Block at the level of the lens
 - a. Phacomorphic glaucoma (swollen lens)
7. Block at the level of the vitreous (malignant glaucoma)

Components may include:

 - a. Previous acute or chronic angle closure
 - b. Anterior chamber shallowing
 - c. Forward lens movement (zonules intact)
 - d. Pupil block by lens or vitreous
 - e. Zonular laxity
 - f. Anterior rotation/swelling of ciliary body
 - g. Expansion of vitreous
 - h. Posterior aqueous misdirection into or behind vitreous
 - i. Choroidal effusion
8. Combined mechanism: more than one level is affected; often posterior lesions also affect a preceding level
9. Low-tension glaucoma: abnormally flexible lamina cribrosa may deform even at a normal intraocular pressure
10. Idiopathic mechanisms

98% of the time. Uveitis and neoplasia were common causes of secondary glaucoma in retrospective referral center studies, but the most common form of glaucoma in cats 7 years of age or older in the prospective private practice population study was that secondary to misdirection of aqueous humor into the vitreous cavity.

Glaucoma may affect one or both eyes, with secondary glaucoma tending to be unilateral, whereas primary glaucoma is almost invariably bilateral. Most cats affected with glaucoma are older (with the obvious exception of

the congenital forms) with an average age of 9.2 ± 4.4 years in one study (Blocker et al., 2001). Several breed predispositions exist. Primary “narrow-to-closed” angle glaucoma was reported in six female Burmese cats aged 7 to 10.5 years, but the classic primary angle-closure glaucoma commonly seen in dogs is very rare to nonexistent in cats. Congenital primary open-angle glaucoma has also been described in a family of Siamese cats. However, the vast majority of cats with glaucoma are domestic shorthairs and longhairs, and any breed of cat is at risk. With the exception of the Burmese report there appears to be no sex predisposition, although there is a trend for uveitis-associated secondary glaucoma to be more common in males since their lifestyle places them at greater risk of exposure to the infectious causes of uveitis (see Chapter 262).

WHAT IS NORMAL FELINE INTRAOCULAR PRESSURE?

Normal feline IOP varies with the time of day (several millimeters of mercury higher at night) and the cat's age. It is also not the same as a dog's normal IOP; values for normal IOP in young adult cats are 20.2 ± 5.5 mm Hg (mean \pm SD). These are higher values than reported in young dogs (16.8 ± 4 mm Hg, Tono-Pen tonometer). A large study of 538 cats (1068 eyes) 7 years of age or older found a mean normal IOP of 12.3 ± 4 mm Hg (Fig. 263-1). Seventy-eight of these cats (154 eyes) were followed over time, and IOP decreased as much as 1.7 mm Hg/year in these cats. The reason for this is unclear, but it may be related to their declining metabolic health and a subsequent reduction in the active secretion of aqueous humor. Therefore normal feline IOP appears to vary with age such that young cats may have a normal upper limit as high as 31 mm Hg, whereas older cats normally do not exceed 21 mm Hg very frequently. Because IOP declines with age in cats, many old cats can have a very low IOP (≤ 7 mm Hg) in the absence of any signs of anterior uveitis.

CLINICAL SIGNS OF FELINE GLAUCOMA

The clinical signs of glaucoma in cats are more subtle than in dogs, at least initially. The acute, congestive form

Fig. 263-1 Intraocular pressure (IOP) measurements from 1068 eyes (538 cats) 7 years or older who underwent IOP screening as part of a senior health care profile. (From Kroll MM, Miller, and Rodan: *J Am Vet Med Assoc* 219:1406, 2001.)

of glaucoma seen in dogs in which IOP rises above 50 to 60 mm Hg in a matter of hours is virtually nonexistent in cats. Instead feline glaucoma is often characterized by slow, insidious increases in IOP with minimal, if any, clinical signs until the disease is advanced. In many cats the only externally visible signs are mydriasis (and associated anisocoria), subtle corneal edema, or buphthalmia. Often clinical signs attributable to the primary inciting cause (e.g., uveitis, intraocular neoplasia) are more prominent than the signs attributable to the increased IOP itself. The overt ocular hyperemia and corneal edema that are common in dogs are usually not seen in cats until IOP is quite high. Unfortunately, by the time clinical signs become apparent, irreparable damage to the optic nerve usually has occurred, and 73% of cats with overt signs of glaucoma were blind at initial presentation to a referral center. In contrast, in a private practice setting in which cats 7 years of age or older were screened for glaucoma, a considerably higher percentage of cats retain vision, presumably related to earlier diagnosis. The subtle nature of glaucoma in cats suggests that IOP should be measured in every cat with intraocular disease, anisocoria, mydriasis, or corneal edema (see Chapter 248).

The hallmark of glaucomatous damage and the cause of irreversible vision loss is posterior bowing or “cupping” of the optic disc. As IOP increases, the pores in the sclera through which retinal ganglion cell axons pass (lamina cribrosa) become distorted. Although this distortion is initially quite small and difficult to appreciate clinically, it pinches the nerve fibers at the lamina, disrupting the normal axoplasmic flow of a variety of nutrients and neurotrophic growth factors. Loss of these factors, especially brain-derived neurotrophic growth factor (BDNF), perhaps coupled with impaired blood flow to the optic nerve, causes retinal ganglion cells to die. Clinically apparent optic disc cupping is the result of loss of retinal ganglion cell axons since these are the structures that comprise much of the optic disc. Dying ganglion cells also release excitotoxins such as glutamate, which can then induce adjacent, otherwise normal ganglion cells to undergo apoptosis; and a vicious cycle of cell death is initiated. Therefore, once increased IOP initiates retinal ganglion cell death, the process can become self-perpetuating and continue even if IOP returns to normal. However, this discouraging series of events does allow for the possibility of a variety of novel therapies for glaucoma that extend beyond lowering IOP. Although still experimental, retinal ganglion cell death can be prevented or reduced (in some cases even without reducing IOP) by treatment with a variety of neurotrophic factors, stress proteins, and antiapoptotic compounds.

In humans glaucoma is monitored not only by following IOP but also by carefully determining whether there is progression in the degree of optic disc cupping and measuring the extent of the patient's visual field. However, determining the amount or progression of optic disc cupping in cats is difficult because the normal feline optic disc typically lacks myelin and appears as a circular, dark grey structure that is depressed from the fundus surface. In addition, changes in the appearance of the disc tend to be slowly progressive if the IOP rise is mild to modest. Therefore, when a cat is first diagnosed with glaucoma,

it is important to examine the optic disc in detail and to use high magnification on follow-up examinations to assess the depth of the cup and changes in the appearance of the laminar pores (normally visible as small, dark dots in the optic disc), as well as whether there are any changes in the reflectivity of the tissues around the optic disc. The normal feline optic disc may have a partial or complete hyperreflective ring (conus) or hyperpigmented ring around its perimeter. However, a change in these normal variations is very suggestive of ongoing glaucomatous damage. Methods for precisely measuring a cat's visual field as is done in humans do not yet exist, and qualitative assessment of a cat's visual abilities through maze testing or the presence of a menace response provides only a very coarse estimate of the adequacy of therapy.

SCREENING CATS FOR GLAUCOMA

The slow, insidious rise in IOP and relatively paucity of overt clinical signs until vision is substantially impaired in older cats suggests that glaucoma screening may have some value as part of a feline geriatric health profile. False negatives and false positives complicate glaucoma screening, but these can be reduced greatly by good technique (see Chapter 248), following up mild elevations with repeated measurements on another day (before instituting therapy), and performing an ophthalmic examination in conjunction with measuring IOP. Based on a study of 538 cats 7 years of age or older (1068 eyes) screened as part of a routine feline geriatric health profile, an IOP of 28 mm Hg or higher or a difference of 12 mm Hg or more between eyes was found to be highly suggestive of abnormally high IOP. However, only approximately 1% of cats 7 years or older have glaucoma, making screening for this disease a relatively low-yield procedure. Causes of abnormally high IOP in this population were presumed to be aqueous misdirection in four cats and a subluxated cataract in one cat (Kroll et al., 2001).

MEDICAL THERAPY FOR GLAUCOMA IN CATS

Pain relief is a key feature of glaucoma therapy in cats. Mild IOP increases typically are not painful, but increases to 40 mm Hg or greater typically cause humans to complain of headaches that may be of migraine intensity when IOP is higher than 60 mm Hg. Although many cats with glaucoma do not exhibit clinical signs that most owners would associate with pain, careful questioning typically reveals that the cat sleeps more, is less active, hides more, or eats less. Returning IOP into the normal range almost invariably causes the owner to comment that the cat "acts like a new cat," adding further evidence to the notion that cats with IOP above 40 mm Hg do have ocular pain. Lowering IOP is the most effective analgesic in these cats, although short-term use of a variety of systemic analgesics such as oxymorphone (0.05 to 0.1 mg/kg), buprenorphine (0.01 to 0.02 mg/kg), or meloxicam (0.3 mg/kg) may also be helpful.

Ideally medical therapy for glaucoma in cats would identify the exact cause and location(s) of the impediment(s) to aqueous humor outflow and circumvent those blocks. Because of the high frequency of secondary glaucoma in cats (especially uveitis-induced glaucoma), many cats with glaucoma can be controlled with medication alone. However, cats often respond very differently than do other species to many of the commercial antiglaucoma drugs, and no single drug is appropriate for all forms of glaucoma in cats. Five classes of antiglaucoma drugs are available: carbonic anhydrase inhibitors (CAIs), β -adrenergic blockers, β -adrenergic agonists, cholinergics, and prostaglandins (PGs) (Table 263-1).

Carbonic Anhydrase Inhibitors

Inhibition of the enzyme carbonic anhydrase lowers IOP by reducing the active production of aqueous humor. Systemic CAIs such as dichlorphenamide, methazolamide,

Table 263-1

Common Antiglaucoma Drugs for Use in Cats*

Drug	Class	Route	Frequency	Mechanism
Dorzolamide 2%	Carbonic anhydrase inhibitor (CAI)	Topical	q8 h	↓ Production
Brinzolamide 1%	CAI	Topical	q8 h	↓ Production
Methazolamide	CAI	Oral	1-2 mg/kg q8-24 h	↓ Production
Dichlorphenamide	CAI	Oral	1-2 mg/kg q8-24 h	↓ Production
Timolol 0.5%	β -Blocker	Topical	q12 h	↓ Production
Betaxolol 0.5%	β -Blocker	Topical	q12 h	↓ Production
Epinephrine 1%-2%	β -Adrenergic agonist	Topical	q6-12 h	↑ Outflow ↓ Production
Dipivefrin 0.1%	β -Adrenergic agonist	Topical	q6-12 h	↑ Outflow ↓ Production
Pilocarpine 2%	Cholinergic	Topical	q6-12 h	↓ Outflow
Demecarium bromide 0.125%	Cholinergic (organophosphate)	Topical	q12-24 h	↓ Outflow

*Proposed mechanism for reduction of intraocular pressure and suggested feline dosages are indicated. Safety of these compounds is not well studied in cats, and frequency of therapy indicated in this table may not be appropriate for all cats with glaucoma. The commercially available prostaglandin derivatives are ineffective in cats.

and acetazolamide have been used for decades; but their value is limited by their systemic toxicity, which includes metabolic acidosis, panting, hypokalemia, gastrointestinal upset, changes in mentation, and blood dyscrasias. Recently topical CAIs such as 2% dorzolamide (Trusopt, Merck), 2% dorzolamide plus 0.5% timolol (Cosopt, Merck), and 1% brinzolamide (Azopt, Alcon) have become available commercially. These compounds have largely supplanted the systemic CAIs in humans and animals. The main advantage of brinzolamide is that it may be less irritating than dorzolamide. Because almost total inhibition of the enzyme is necessary to lower aqueous humor production, topical CAIs probably need to be administered every 8 hours to be effective. There is little published work with these compounds in cats, but 1% brinzolamide every 12 hours did not lower IOP significantly in normal cats, perhaps because of inadequate dosing frequency. However, dorzolamide 2% every 8 hours markedly lowered IOP in Siamese cats with primary open-angle glaucoma and in cats with feline aqueous humor misdirection syndrome (FAHMS). Drugs in this class are additive to all other antiglaucoma drugs and do not exacerbate anterior uveitis.

β -Adrenergic Blockers

Drugs such as 0.25% to 0.5% timolol maleate (a nonspecific β_1 -, β_2 - adrenergic antagonist) and 0.5% betaxolol HCL (a cardioselective β_1 -adrenergic antagonist) appear to work by reducing aqueous humor production in cats. However, a certain level of adrenergic tone is required for them to be effective; and they do not lower IOP during sleep, which can be problematic given the amount of time cats spend sleeping. Topical nonsteroidal antiinflammatory drugs (NSAIDs) are also experimentally capable of preventing timolol from lowering IOP in cats, suggesting that PGs may also play a role in the mechanism of action of these drugs in cats. Nevertheless, a single topical application of 0.5% timolol maleate reduced IOP 22.3% in the treated eye and 16.3% in the nontreated eye in normal cats. For reasons that are not entirely clear, timolol causes miosis in cats. Topical timolol may also cause bradycardia and worsening of asthma in cats. Although recent work suggests that β_2 -receptors are the most prevalent in the cat's anterior segment, betaxolol (which blocks β_1 - receptors) may still be of benefit to cats with glaucoma even if it does not lower IOP. Recent work has shown that topically applied betaxolol can reach the retina and optic nerve and that experimentally it improves retinal blood flow and electrical responsiveness in cats with elevated IOP. Because β -adrenergic blockers do not exacerbate uveitis, they are good choices for treating cats with uveitis-induced glaucoma as long as they are not used concurrently with NSAIDs. Drugs in this class are also additive to all classes of antiglaucoma drugs, with the possible exception of the β -adrenergic agonists.

β -Adrenergic Agonists

Drugs such as 1% to 2% epinephrine or its prodrug 0.1% dipivefrin appear to lower IOP in cats by increasing conventional outflow and perhaps by decreasing aqueous

humor production. Topical 2% epinephrine HCL every 12 hours for 1 week lowered IOP 27% in normal cats. Drugs in this class may be irritating because they vasoconstrict the ocular surface. Their efficacy tends to decrease with time, and their effect can be partially blocked by topical NSAIDs. They are additive to cholinergics and carbonic anhydrase inhibitors but poorly additive to β -adrenergic blockers. Because they do not exacerbate uveitis and may induce mild pupillary dilation, drugs in this group are good choices for treating cats with uveitis-induced glaucoma. The commercially available α_2 -agonist apraclonidine 0.5% (Iopidine, Alcon) is unacceptably toxic to cats.

Cholinergics

Drugs such as 2% pilocarpine (which mimics acetylcholine) or 0.125% demecarium bromide (which inhibits acetylcholinesterase) lower IOP in cats by improving conventional outflow. One application of 2% pilocarpine in normal cats lowered IOP 15.2% in the treated eye and 9.3% in the nontreated eye and reduced pupil diameter 28.5% in the treated eye and 14.2% in the nontreated eye. Like the β -adrenergic agonists, drugs in this class tend to lose efficacy with time, and side effects include ocular irritation. Cholinergics should be used cautiously in uveitis-induced glaucoma because they can exacerbate uveitis and the miosis they create may increase the risk of iris bombé. They are additive to drugs in every other class, although demecarium bromide may inhibit corneal esterases that convert dipivefrin to its active form.

Prostaglandin Derivatives

The IOP-lowering effect of the PG derivatives is highly dependent on subtle variations in the molecule, its concentration, and the species tested. They probably lower IOP by increasing uveoscleral outflow and perhaps by reducing aqueous humor production. Unfortunately in multiple studies the commercially available $\text{PGF}_2\alpha$ derivatives such as latanoprost 0.005% (Xalatan, Pfizer), bimatoprost 0.03% (Lumigan, Allergan), unoprostone 0.12% (Rescula, Novartis), and travoprost 0.004% (Travatan, Alcon) do not lower IOP in cats, although they do induce a marked miosis. Although the commercially available PGs are disappointing in cats, this class of drug is promising because experimentally certain PGE_2 and PGA_2 derivatives were well tolerated and highly effective in cats but were discontinued because of lack of efficacy or unacceptable side effects in monkeys or humans.

DRUGS THAT MAY INCREASE INTRAOCULAR PRESSURE IN CATS

Topical 10% phenylephrine (an α_1 -adrenergic agonist) that is sometimes used as a mydriatic in cats can inhibit aqueous humor outflow by 67%, which may increase IOP in cats. Another topical mydriatic, tropicamide (an anticholinergic), can markedly increase IOP in both the treated and untreated eye of normal cats (a mean of 3.5 mm Hg, but up to 17 to 18 mm Hg in select individuals) and in cats with primary open-angle glaucoma, even though it dilates the pupil in only the treated eye. Topical

0.1% dexamethasone or 1% prednisolone acetate two to three times a day caused a 4.5-mm Hg gradual increase in IOP in normal cats beginning within 5 to 7 days and reaching peak values within 2 to 3 weeks. IOP returned to baseline values in 6 to 7 days with cessation of therapy. Therefore, when treating cats with uveitis-induced glaucoma, the clinician must weigh the potential increase in IOP caused by use of certain mydriatics or corticosteroids against the potential decreases in IOP caused by the prevention of iris bombé and the reduction of the inflammatory debris from the outflow pathways.

SURGICAL THERAPY FOR FELINE GLAUCOMA

Cats may be less amenable to some of the antiglaucoma surgical procedures than dogs. Often the best results are achieved if the cause of the glaucoma can be addressed directly (e.g., removing a luxated lens that is blocking the pupil, disrupting ciliary cysts that are pushing the peripheral iris into the drainage angle, or breaking down posterior synechia that are creating iris bombé). Placement of an artificial tube (gonio-implant) from the anterior chamber into the subconjunctival space may allow the clinician to bypass an obstructed or closed iridocorneal angle, but frequently these devices do not remain patent in the long-term. If the impediment to aqueous humor outflow cannot be addressed directly, IOP may be lowered by destroying a portion of the ciliary body either by freezing (cyclocryosurgery) or by use of a diode or neodymium:yttrium-aluminum-garnet (Nd:YAG) laser (cyclophotocoagulation). Protocols for treating glaucomatous cats are not well established, but experimentally a 30% reduction in IOP could be achieved in normal cats by transsclerally freezing 12 spots for 1 minute to -80°C or by 80 noncontact Nd:YAG laser applications over 360 degrees 3 mm posterior to the limbus, with a maximum power of 7 to 9 joules and a maximum retrofocus of 3.6 mm. Often IOP tends to creep back up after a cyclodestructive procedure has been performed, necessitating that it be repeated. Cyclodestructive procedures incite considerable uveitis and are probably best reserved for cats with primary glaucoma or nonneoplastic glaucomas when another procedure cannot correct the problem (e.g., removal of a luxated lens). Intravitreal injection of gentamicin to destroy the ciliary body chemically is probably contraindicated in cats because of anecdotal reports of intraocular tumors after this procedure.

If the eye is irreversibly blind and painful, evisceration and placement of an intrascleral prosthesis or enucleation may be considered. Although evisceration and insertion of an intrascleral prosthesis is technically feasible in cats, the cosmetic results achieved with dark-colored spheres are often less successful than in dogs. This has led some to use colored spheres and to tattoo a slit pupil onto the cornea in an effort to improve the final postoperative cosmetic appearance of the eye. Cats tolerate enucleation well, and a silicone sphere may be implanted into the orbit before skin closure to minimize the degree of "sinking in" that typically occurs following removal of the globe. The suggested rejection rate of these spheres in cats, however, may exceed that in dogs.

THERAPY FOR SPECIFIC FORMS OF GLAUCOMA IN CATS

Primary Glaucomas

Primary open-angle glaucoma tends to be congenital in cats and difficult to control medically for very long. In the early stages topical CAIs alone or in combination with a topical β -adrenergic blocker can be used. The addition of a β -adrenergic agonist may also afford an additional reduction in IOP of a few millimeters of mercury. However, surgical therapy usually becomes necessary. A cyclodestructive procedure with or without a gonio-implant may allow vision to be maintained for some time in some of these cats. Fortunately acute primary-angle closure glaucoma is rare in cats. Although there are no data to support any treatment regimen in these patients, it is likely that a cyclodestructive procedure with or without a gonio-implant would be required early in the course of the disease to preserve vision.

Uveitis-Induced Glaucoma

Cats with normal IOP in the face of uveitis are at high risk for developing glaucoma because aqueous humor production (and IOP) is normally low in uveitis. Therefore normal IOP means that the outflow pathways are impaired and that IOP may spike upward as the uveitis is controlled. Uveitis that is severe enough to result in glaucoma merits thorough diagnostic investigation for a potential systemic cause unless the cause is obvious (see Chapter 262). If the eye has vision or the potential for vision, rapid and aggressive antiinflammatory therapy with topical corticosteroids (0.1% dexamethasone or 1% prednisolone acetate q4h) is usually indicated if the cornea is not ulcerated. If not contraindicated, antiinflammatory-to-immunosuppressive doses of systemic corticosteroids should also be considered. Topical CAIs, β -adrenergic blockers, or β -adrenergic agonists are reasonable first choices since they do not exacerbate uveitis. In general, atropine or tropicamide is not used unless the impediment to outflow is caused by posterior synechia and it is believed that breaking these down and reestablishing normal flow of aqueous humor through the pupil is possible. Antiglaucoma drugs are tapered slowly as the uveitis resolves and IOP normalizes, although severe cases may require long-term therapy to preserve vision. Enucleation or evisceration with placement of an intrascleral prosthesis (and histopathologic examination of the excised tissue) is reasonable if the eye is irreversibly blind and painful. In general, the prognosis for vision in cats with uveitis-induced glaucoma is guarded.

Neoplasia-Associated Glaucoma

In the majority of patients with glaucoma secondary to intraocular neoplasia, the only viable options are to stage the tumor and then perform enucleation, or if appropriate, systemic chemotherapy. Enucleation, even if only palliative, alleviates ocular pain and may substantially

improve the cat's overall quality of life. In some cats with secondary glaucoma caused by intraocular lymphosarcoma, IOP may normalize with a combination of systemic chemotherapy, aggressive use of topical corticosteroids (0.1% dexamethasone or 1% prednisolone acetate four to six times daily), and a topical CAI or a β -adrenergic blocker. If the tumor is confined to the eye, drugs that increase outflow via the traditional pathway (e.g., cholinergics and β -adrenergic agonists) probably should be used cautiously since they may facilitate neoplastic cells leaving the globe.

Glaucoma Secondary to Anterior Lens Luxation

The relationship between glaucoma, lens luxation, and uveitis in cats is often complicated; and any one of these three disorders may be primary and result in the other two disorders. Often it is difficult, if not impossible, to determine the exact sequence of events, especially in patients seen for the first time in the late stages of the disease; but ideally the temporal relationship between these three disorders would be established in each patient since therapy tends to be different in each scenario. If the eye is irreversibly blind, enucleation or evisceration with placement of an intrascleral prosthesis (and histopathologic examination of the excised tissue) is probably the best therapy. If the eye has the potential for vision, removal of the lens should be considered if it is in the anterior chamber, although glaucoma may persist after surgery if the drainage angle is also impaired. In addition, diagnostic investigation of potential systemic causes of anterior uveitis should be considered if the cause of the uveitis is not readily apparent. If the lens is in the posterior chamber or vitreous, it may be possible to trap it there with a strong miotic such as the organophosphate demecarium bromide (0.125% q12–24h). However, this drug can exacerbate uveitis, and often it does not control the pupil well enough to prevent the lens from entering the anterior chamber and subsequently increasing IOP.

Glaucoma Associated With Hyphema

This form of glaucoma is relatively uncommon in cats and is most frequently associated with massive intraocular hemorrhage caused by systemic hypertension, lymphosarcoma, severe ocular trauma, and rarely blood dyscrasias. Therapy is somewhat controversial but is directed toward identifying the underlying cause of the bleeding and treating that directly. Topical antiglaucoma drugs that do not exacerbate uveitis (CAIs, β -adrenergic agonists) and topical corticosteroids (0.1% dexamethasone or 1% prednisolone acetate) are good first choices. Topical β -adrenergic blockers may also be used, although the miosis these drugs induce may increase the chance of iris bombé. Atropine and tropicamide should be used with caution if glaucoma is present. Persistent or recurrent intraocular bleeding warrants systemic diagnostic testing and ultrasonographic evaluation of the eye to rule out an underlying cause such as retinal detachment, hypertension, coagulopathies, or intraocular tumor. Surgical evacuation of blood from the anterior chamber is usually of very limited value.

FELINE AQUEOUS HUMOR MISDIRECTION SYNDROME

This recently described entity affects up to 1% of cats 7 years of age or older and may be the most common form of feline glaucoma in a general private practice setting. Most cats are older (mean age 11.7 years, range 4 to 16 years), and females are predisposed. The hallmark of FAHMS is a uniformly shallow anterior chamber without trembling of the iris/lens or other evidence of lens luxation. The most common presenting clinical signs include anisocoria, bilateral mydriasis, a shallow anterior chamber, incipient cataracts, or impaired vision in one or both eyes (Figs. 263-2 and 263-3). There is no apparent pain unless IOP is significantly elevated, and many owners do not appreciate that anything is wrong until the disease is advanced. Initial IOP varies with the degree of anterior chamber shallowing, and in one case series it was 20 mm Hg or higher in 32/40 eyes, with a range of 12 to 58 mm Hg. Increases in IOP tend to be slow and insidious, and not all affected cats have glaucoma at initial presentation.

The underlying pathophysiology appears to be the misdirection of aqueous humor through presumed microscopic breaks in the membrane forming the anterior face of the vitreous. Blinking may increase IOP in the anterior chamber transiently, and this may be transferred to the posterior chamber and force aqueous humor posteriorly through a small tear in the vitreous face. The tear acts like a one-way valve, allowing aqueous humor to enter but not leave the vitreous. Aqueous may accumulate in a variety of locations within the vitreous (Fig. 263-4) and ultimately displaces the vitreous face anteriorly. This is the first block to aqueous humor leaving the eye. A cascading series of additional impediments to outflow may then occur as (1) the vitreous face is forced between the anterior ciliary body and lens; (2) the lens is pushed anteriorly into greater contact with the posterior surface of the iris; (3) the lens:iris diaphragm moves forward, closing the iridocorneal angle; and (4) the ciliary cleft closes. It is easy to understand why advanced stages of this disorder are difficult to treat effectively.

If the eye has vision and the IOP elevation is relatively mild, there is a reasonable chance that IOP may

Fig. 263-2 Clinical appearance of a cat with overt feline aqueous humor misdirection syndrome (FAHMS) in the left eye and suspected early FAHMS in the right eye. Both pupils are relatively dilated, but there is anisocoria, with the left pupil larger than the right. (From Czederpiltz JMC et al: *J Am Vet Med Assoc* 227:1476, 2005.)

Fig. 263-3 Lateral view of a FAHMS-affected cat (**A**) and normal cat (**B**). Note the extremely shallow anterior chamber in the FAHMS-affected eye. (From Czederpiltz JMC et al: *J Am Vet Med Assoc* 227:1476, 2005.)

be controlled with a topical CAI for the remainder of the cat's life. Cats that lose vision tend to have very advanced disease at initial presentation or have rapidly progressive disease. Other antiglaucoma drugs besides topical CAIs may also be effective, but miosis can increase the block at the iris:lens interface and rapidly increase IOP to very high levels. If medical therapy is ineffective, anterior

vitrectomy and lensectomy may reestablish a more normal outflow pathway, provided more anterior blocks at the iridocorneal angle or ciliary cleft have not occurred.

Retinal Detachment

PATRICIA J. SMITH, *Fremont, California*

PATHOGENESIS

A retinal detachment (RD) is a separation of the neurosensory retina from the retinal pigment epithelium (RPE). In the normal eye the vitreous, retina, and lens are connected by various physical and chemical mechanisms. RDs may be caused by at least one of three main mechanisms: exudation (nonrhegmatogenous), associated with retinal tears (rhegmatogenous), or traction pulling on the retina. Complicated RDs are those that involve more than one of the main mechanisms (e.g., a retinal tear or hole that results from a vitreous traction band).

In small animals most RDs are exudative. The subretinal fluid is usually inflammatory but can be serous with diseases such as systemic hypertension or (see Chapters 159 and 197). The subretinal fluid typically results from breakdown of the blood-ocular barrier in the retinal and choroidal vasculature. Because the choroidal vascular bed is much larger than the retinal vascular supply, a large amount of subretinal fluid usually indicates diffuse choroidal involvement; as seen with diseases such as chorioretinitis, systemic hypertension, or hyperviscosity. Initially areas of chorioretinitis appear as variably sized focal or multifocal areas of retinal elevation with indistinct borders. These active areas of chorioretinitis alter the course of the overlying retinal blood vessels and obscure or blur the ophthalmoscopic view of the underlying RPE or tapetum as shown in Fig. 264-1. (For a discussion of the cause of RDs from posterior uveitis, see Chapter 262.)

Rhegmatogenous RD is associated with formation of one or more retinal tears or holes. This type of RD is less common than exudative RD in small animals and occurs more commonly in dogs than in cats. The pathogenesis of rhegmatogenous RD involves the presence of an abnormal retina (i.e., thinned as a result of degeneration, age, or other diseases), which is predisposed to formation of tears or holes, combined with an abnormal vitreous as with vitreous syneresis (liquefaction), traction, or detachment. The vitreous gel is a homogeneous collagen fibril network with hyaluronic acid molecules filling the interfibrillar space. The vitreous is more firmly attached in three locations: the peripheral posterior lens capsule, the vitreous base that overlies the peripheral edge of the retina (the pars plana and ora ciliaris retina), and the margin of the optic nerve. Since the vitreous hydrogel is attached to the lens and retina, perturbations of the vitreous (e.g., inflammation, surgery) or lens can contribute to the development of rhegmatogenous RD by creating retinal traction, which can lead to tear or hole formation. Liquid from the vitreous then moves through the hole or tear into the subretinal space and exacerbates the RD.

ETIOLOGY

Despite the multiple causes of RD, consideration of the type of RD (exudative, traction, or rhegmatogenous), the nature of any subretinal fluid, and whether the detachments are unilateral or bilateral assist with differentiating or prioritizing the likely causes. Although bilateral RD is strongly suggestive of systemic disease or congenital ocular disease, unilateral detachment should not cause these considerations to be disregarded. Serous subretinal fluid with or without hemorrhage is more common with hypertension, hyperviscosity syndromes, and rickettsial disease. When subretinal fluid is opaque as a result of marked cellular infiltrate, causes of exudative disease such as lymphosarcoma, idiopathic inflammatory, uveodermatologic syndrome, and fungal infections should be considered more likely.

Trauma

Penetrating injuries (e.g., dog bites, projectiles) or foreign bodies may result in retinal tears or induce intraocular hemorrhage, inflammation, or vitreous infection with subsequent traction RD. Severe blunt trauma with inflammation and hemorrhage may also cause RD, which may be exudative or rhegmatogenous in nature. However, it is extremely unlikely for a traumatic incident to cause RD in both eyes. The exception is strangulation, which can lead to bilateral exudative (hemorrhagic) RD.

Ocular Anomalies

RD may be associated with severe retinal dysplasia, optic nerve colobomas, vitreous abnormalities, and retinal nonattachment (i.e., developmental failure of the two retinal layers to unite). Animals with RD present at or soon after birth, often having concurrent abnormalities such as microphthalmia or cataracts. Detachment may be unilateral or bilateral.

Later onset genetic anomalies such as cataracts or vitreous degeneration may lead to RD. Rhegmatogenous RD also may occur as a result of vitreous liquefaction or cataract formation, particularly with rapidly forming or hypermature cataracts or when there is lens-induced uveitis. Rhegmatogenous RD may occur as a sequela to cataract surgery (reported incidence 1% to 4%) or lens luxation or subluxation. When an RD is evident but without a history of trauma, cataracts, or lens surgery, a thorough diagnostic workup is indicated to identify predisposing systemic diseases.

Fig. 264-1 Chorioretinitis in a dog caused by blastomycosis. Small areas of active chorioretinitis are associated with focal, low retinal detachments.

Hypertension/Hyperviscosity

Systemic hypertension (most often related to renal diseases) and hyperviscosity syndromes (caused by severe hyperlipidemia, hyperglobulinemia, or polycythemia) are relatively frequent causes of RD. These diseases typically damage the vasculature of the choroid and retina, creating hemorrhage in the retina and sometimes in the vitreous. Renal failure with secondary hypertension is probably one of the most common causes of bilateral RD in older cats. Hyperthyroidism and pheochromocytoma also should be considered as causes of hypertension, which can lead to bilateral RD.

Neoplasia

The most common neoplastic causes of RD are multiple myeloma (in which hyperproteinemia and hyperviscosity damage retinal and choroidal vasculature) and lymphosarcoma (which may diffusely infiltrate the retina or choroid). Patients with lymphosarcoma also may present with retinal hemorrhage with or without detachment and anterior uveitis. Each of these neoplasms is likely to affect both eyes. Large neoplastic masses (e.g., ciliary body iridal tumors) or metastatic lesions may induce traction RDs. If neoplastic tissue is subretinal or choroidal, exudative RD is more likely to be unilateral.

Chorioretinitis/Retinochoroiditis

Retinochoroiditis is used to imply that retinal tissue was inflamed primarily with secondary choroidal inflammation, whereas the inverse is true for the term *chorioretinitis*. Retinitis or chorioretinitis may cause focal or multifocal RDs. As discussed previously, small areas of inflammation are technically RDs, but this type of lesion is best termed *chorioretinitis* (see Chapter 262). When choroidal inflammation is severe and diffuse, large segmental or complete RDs may occur. In the dog chorioretinitis with RD may be caused by bacteremia or septicemia (e.g., leptospirosis, brucellosis, bartonellosis), rickettsial agents (ehrlichiosis,

Rocky Mountain spotted fever agent), fungal organisms (aspergillosis, blastomycosis, coccidioidomycosis, histoplasmosis, cryptococcosis), algae (geotrichosis, protothecosis), and rarely today canine distemper virus. Parasitic inflammation of the choroid and retina is more likely to cause smaller areas of detachments (i.e., multifocal chorioretinitis). Causes include ocular larval migrans (from strongyles, ascarid, *Baylisascaris* larvae), toxoplasmosis, leishmaniasis, neospora, and possibly *Babesia*. In cats infection with feline leukemia and/or immunodeficiency viruses may indirectly cause chorioretinitis-related development of lymphosarcoma or an opportunistic infection such as toxoplasmosis. Feline infectious peritonitis virus is a more common cause of small-to-large areas of chorioretinitis and possibly RD. As in dogs, any systemic bacterial, parasitic, or fungal infection can cause areas of chorioretinitis or diffuse RD.

Immune-Mediated Disease

Immune-mediated disease can cause vasculitis with or without choroidal inflammation; this can lead to exudative RD or chorioretinitis. In dogs systemic lupus erythematosus and uveodermatologic syndrome may result in exudative detachment. Uveodermatologic syndrome is an autoimmune disease directed against melanin. The uvea of pigmented eyes is targeted, resulting in severe anterior and posterior uveitis and RDs. Pigmented cells in the skin are also injured such that affected animals can have mucocutaneous (and later diffuse) dermatitis with eventual depigmentation. I see uveodermatologic syndrome more commonly in arctic breeds such as Akitas, Siberian huskies, and chow-chows, but it also has been reported in other breeds. Granulomatous meningoencephalitis may also cause RD, usually in the peripapillary region and in association with optic neuritis and other signs of central nervous system disease. Idiopathic RD is diagnosed after thorough investigation rules out all other etiologies and the ophthalmic history and examination rule out retinal tears. I diagnose this type of detachment in dogs (especially giant breeds) but rarely in cats. Idiosyncratic reactions to drugs (i.e., trimethoprim-sulfa in dogs, griseofulvin in cats) and ethylene glycol toxicity in dogs may induce RD and multifocal chorioretinitis. There have been isolated reports of retinal diseases in cats from periarteritis nodosa and systemic lupus erythematosus.

DIAGNOSIS

A thorough history should determine if any of the following might be relevant: trauma, swimming in ponds (*Prototheca*), feeding of raw fish (salmon poisoning) or mammalian carcasses (*Salmonella*, parasites), exposure to ticks, or travel history to areas endemic for some of the aforementioned infectious diseases. A complete general physical examination should be undertaken. A thorough ophthalmic examination should be conducted with special attention to intraocular pressure, pupillary light reflexes and menace responses, aqueous flare, lens changes, and indirect and direct ophthalmoscopy of the retina. A systematic approach enables the clinician to diagnose chorioretinitis, RD, and possibly panuveitis if anterior uveitis is present (see Chapter 248).

Fig. 264-2 Serous retinal detachment in a cat with hypertensive retinopathy. On fundic examination areas of retinal detachment may be elevated to different degrees. The examiner should note that vessels and the optic nerve are in different planes of focus. The subretinal fluid is transudative (more translucent) in this cat; thus the tapetal color is still visible. Serous retinal fluid is also commonly seen with vasculitis and immune-mediated retinal detachments.

Fig. 264-3 Exudative retinal detachment in a dog. This type of subretinal fluid is more commonly seen with infectious or neoplastic diseases. The exudative fluid obscures view of the normal tapetal and nontapetal colors. This type of subretinal fluid is more detrimental to retinal health than is serous fluid. Even if the etiology is identified and treated, the retina often degenerates quickly so that visual recovery is unlikely even if reattachment occurs.

When a large RD is present, the pupillary light reflex is absent or reduced in the affected eye. With retinal elevation the retinal blood vessels are in focus at a different plane than the optic nerve. If the retina is markedly elevated, a membrane with blood vessels may be visible through the pupil during anterior segment examination. With serous subretinal fluid the underlying RPE, or in subalbinotic animals the choroidal vasculature, is not clearly visualized in the nontapetal region; and a similar dulling of the tapetal region occurs (Fig. 264-2). With severe exudation, a turbid subretinal fluid obscures the view of the normal tapetum and nontapetum (Fig. 264-3). Rhegmatogenous RD may reveal a visible retinal tear or break (Fig. 264-4). If opacification of the cornea, aqueous, lens, or vitreous caused by anterior uveitis or cataract prevents visualization of the retina, ocular ultrasonography can be used to diagnose RD.

If systemic disease is suspected, a complete blood count, serum biochemistry panel, and urinalysis are important initial tests. The results of these tests may point toward an etiology and direct additional tests. For example, if an animal with RD has marked hyperglobulinemia, protein electrophoresis, radiographs of the limbs and spine, and documentation of Bence-Jones proteinuria should be performed, which might lead to a diagnosis of multiple myeloma. Serologic, enzyme-linked immunosorbent assay or polymerase chain reaction-based tests for infective agents may be useful in some cases. Cats should be evaluated for feline immunodeficiency virus and feline leukemia virus infection. Blood pressure should be measured in cases of serous RDs with or without hemorrhage, especially if renal disease or hyperthyroidism is evident.

Repeated blood pressure measurements should be performed if initial blood pressure is normal but hypertension is still suspected, especially in cases of bilateral disease. Additional tests that might be pursued include coagulation profile and cultures and cytology of ocular or body fluids. A dog with panuveitis and mucocutaneous lesions (especially

Fig. 264-4 Rhegmatogenous retinal detachment in a dog that had previously undergone cataract surgery. The edge of the torn retina can be visualized through the pupil in this case. This type of retinal detachment should be treated surgically.

if depigmentation is prevalent) should have the skin lesions biopsied, especially of susceptible breeds (Akita, chow-chow, Samoyed). An antinuclear antibody test may be performed if lupus erythematosus is suspected.

Thoracic radiography is a useful screening test to search for lymphadenopathy, metastatic disease, or infiltrates consistent with infectious agents. Cardiac ultrasound may be indicated in cats with hypertensive retinopathy. Abdominal ultrasound also can add information that may help with the diagnosis if it reveals abnormalities in the organs or peritoneal space such as adrenal masses or lymphadenopathy. Abdominal radiographs may be useful; but abdominal ultrasound is superior for evaluation of the kidneys, adrenal glands, and other organs.

Analysis of cerebrospinal fluid is indicated if signs of central nervous system disease or optic neuritis are present. Vitreocentesis or subretinal fluid aspiration can be performed if other diagnostic tests have failed to yield an etiologic agent and an infectious agent or neoplastic disease is suspected. However, vitreocentesis can aggravate intraocular inflammation or induce vitreous hemorrhage, decreasing the chance of retinal reattachment and restoration of vision. Thus the pros and cons of this procedure should be discussed with the owner. If an eye is irreversibly blind and painful, enucleation with subsequent histopathologic examination may yield a diagnosis.

TREATMENT

Exudative Retinal Detachment

Exudative RD is treated medically by identifying and treating the underlying cause. This may include antimicrobial therapy for bacterial or antifungals for fungal-related infections. In deep organ or bone infection or when abscesses are present, surgical intervention may also be indicated. If systemic hypertension is the cause of an RD, appropriate antihypertensive therapy should be used. Amlodipine is generally the most effective drug for treatment of severe hypertension in cats and dogs (see Chapters 159 and 197). If neoplastic disease is amenable to chemotherapy, it should be treated appropriately.

Resolution of the underlying cause of RD sometimes leads to spontaneous retinal reattachment, especially if the fluid is relatively serous. However, if an inflammatory cause is diagnosed or there is severe chorioretinal inflammation (with a cellular subretinal fluid), it may be necessary to use systemic corticosteroid treatment in conjunction with treatment of the primary disease. The longer a retina is detached and the more turbid the subretinal fluid, the faster the retina degenerates, with consequences of irreversible blindness or vision loss. Systemic steroid use can hasten reattachment; however, it is extremely important to eliminate or concurrently treat diseases such as a systemic mycosis since infections may be exacerbated by systemic steroid administration. If the patient appears to be irreversibly blind and especially if secondary glaucoma is present, enucleation or evisceration may be the best course to minimize systemic steroid use until the definitive cause is determined.

Systemic corticosteroids are the treatment of choice for idiopathic or immune-mediated exudative RD such as that caused by uveodermatologic syndrome. I prescribe prednisone (1.1mg/kg orally [PO] q12h for 3 to 7 days); then, if the retina is beginning to reattach, I begin tapering the dose slowly while watching for signs of recurrent inflammation or detachment. If corticosteroid treatment does not rapidly improve the RD, adjunctive immunosuppressive agents such as azathioprine or cyclosporine may be added to the treatment regimen. Side effects such as bone marrow suppression, hepatopathy, and renal toxicity should be monitored closely when these drugs are used. In cases of hypertensive retinopathy I rarely use systemic corticosteroids unless there is a severe uveitis or vitritis secondary to intraocular hemorrhage. These can be difficult cases to manage, and referral to an ophthalmologist should be strongly considered for diagnosis and treatment of any vision-threatening ophthalmic diseases, including RD.

Rhegmatogenous (Nonexudative) Retinal Detachments

In contrast to exudative RD, rhegmatogenous RD or traction RD represent surgical conditions, and these patients should be referred promptly to an ophthalmologist for diagnosis and treatment. This type of detachment is treated by identifying and then sealing all retinal tears or holes. Small detachments may be stabilized by performing a barrier laser retinopexy around the border of the detachment and at the periphery of the retina. Large or complete detachments with giant retinal tears, several holes, or vitreous problems must be repaired surgically. Surgery involves a pars plana vitrectomy, retinal reattachment, laser retinopexy, and typically tamponade with silicone oil to replace the vitreous. Unfortunately not all patients are good candidates for this surgery. Surgical repair requires protracted general anesthesia and extensive postoperative monitoring and is very costly. Depending on the individual eye, the anatomic success rate may be as high as 90%; however, this does not always correlate with a functional success of vision recovery.

PROGNOSIS

The prognosis for a dog or cat with an RD directly relates to the etiology. If there is a life-threatening systemic disease, the prognosis for life is often poor. If there is no life-threatening disease, an animal may become blind or visually impaired or might lose a painful eye but subsequently may live a well-adjusted life. In patients presented with RD and visual impairment, prognosis is guarded. Recovery of vision relates to the promptness of diagnosis and treatment. If the underlying condition can be identified rapidly and treated, the retina may reattach, and some vision may return. However, up to 80% of the retinal nutrition and oxygen supply is derived from the choroidal vasculature. Therefore, as soon as the retina separates from the choroid and RPE, retinal degeneration begins. The nature of the subretinal fluid, duration of detachment, and height of detachment influence the degree and rapidity of retinal

degeneration. Blood or dense exudative subretinal fluid (i.e., systemic mycoses), prolonged RD, and very elevated (bullous) detachment all hasten retinal degeneration and negatively affect visual recovery. Animals with small or partial RD or smaller and/or multifocal areas of chorioretinitis have a fair-to-good prognosis for maintaining some vision if the cause is identified quickly and treated appropriately.

Hospital-Acquired Bacterial Infections

SCOTT P. SHAW, North Grafton, Massachusetts

Hospital-acquired infections (HAIs) are well recognized as a serious source of morbidity and mortality in people. There is a vast and rapidly growing body of knowledge pertaining to HAIs in human patients, but information relating to veterinary HAIs is much more limited. There are several individual case reports of epidemic outbreaks within individual hospitals, but there is little published information on the role endemic hospital infections play in veterinary medicine. Currently there is no evidence-based information that can be used by veterinarians to guide infection-control decisions. Instead recommendations must be made based on the small amount of available veterinary research and extrapolation from the human literature.

HAIs are defined as infections that were neither present nor incubating at the time of hospital admission. Typically these infections develop more than 48 hours after admission because of the incubation period of most hospital-acquired pathogens. Hospital-acquired infections can develop up to 30 days after hospitalization or even a year later if an implant was placed. Although HAIs in veterinary hospitals could reflect pathogens of various types, especially bacterial and viral, bacterial infections are the focus of chapter.

EPIDEMIC VERSUS ENDEMIC INFECTIONS

Epidemic infections result from the infection or contamination of an individual source with a potential pathogen. This point source then results in the infection of one or more other individuals. Examples of epidemic infections reported in veterinary medicine include the infection of feline blood with *Serratia marcesans* from contaminated saline flush and *Salmonella krefeld* infection in numerous small animal patients, which was traced back to a caregiver who was an asymptomatic carrier.

Endemic infections are infections that occur regularly at a low or moderate frequency. These infections differ from epidemic infections in that they are not caused by a single point source. Instead, these infections result from a patient's endogenous flora, which is able to establish an infection because of a combination of debilitation from underlying illness, breaches in normal anatomic barriers (intravenous catheters, endotracheal intubation, surgical incisions), or placement of surgical implants. Endemic infections are much more difficult to eliminate since they do not result from a discrete identifiable source but represent the interplay of numerous risk factors, some of which can be mitigated and some of which cannot.

It is estimated that only 5% of all HAIs in humans represent epidemic outbreaks. The remaining 95% of infections are endemic in origin. Epidemic infections are more likely to be published and receive attention from the general public. As a result, their relative importance tends to be overemphasized. Although not investigated, a similar distribution likely occurs in veterinary patients.

PATHOGENESIS OF ENDEMIC INFECTIONS

Understanding the pathogenesis of endemic infections is essential to devise effective control strategies. During the course of illness the normal nonpathogenic flora of the oropharynx, gastrointestinal tract, and occasionally the skin can be replaced by potential pathogens. The basis for these changes in flora is multifactorial. A number of defense mechanisms such as secretion of immunoglobulin (IgA) antibodies into the oral cavity and respiratory and gastrointestinal tracts, the integrity of the gastrointestinal mucosal barrier, and the presence of normal flora in the oral cavity and gastrointestinal tract protect against colonization by pathogenic bacteria. Critical illness has been shown to decrease IgA secretion, which predisposes the patient to colonization by pathogenic bacteria. In addition, a large number of intensive care unit (ICU) patients receive antimicrobial therapy that disrupts the normal flora to an even greater degree and opens a previously occupied ecologic niche for colonization by pathogens, including some with marked resistance to antimicrobials.

From where do the pathogens that cause HAIs originate? Historically the environment has been implicated as the reservoir for the microbes that cause HAIs. Much time and effort is spent cleaning and culturing the environment in an effort to remove these pathogens, an approach that is still used in some veterinary hospitals. Recently bacterial contamination of multidose drug vials in a veterinary clinic has been demonstrated; although HAIs associated with use of these vials were not the focus of this study, the findings should give users of such vials reason for concern. However, over the last 20 years the focus of infection control in human hospitals has shifted from the environment to the patients and to a lesser extent the staff because the reality is that the major reservoir for potential pathogens in the health care setting is the patient. In most cases positive environmental cultures represent transient contamination of the environment by patients. The pathogens that cause HAIs are transferred from patient to patient,

generally on the hands of caregivers. Once a pathogen is transferred to a patient, colonization is likely for the reasons discussed here.

Reducing the Incidence of Endemic Hospital-Acquired Infections Through Surveillance

An active surveillance program is essential for rapidly recognizing epidemic outbreaks and understanding the incidence of endemic infections. A surveillance program can be relatively simple or complex, depending on the depth of knowledge desired and the personnel and financial resources available. In addition, it has been shown that hospitals with active surveillance programs have a higher rate of adherence to infection control policies. This may be because of a Hawthorne effect (i.e., individuals who know they are being observed behave differently from those who are not aware of the observation).

In addition to observing for the occurrence of HAIs, other information, referred to as denominator data, must be collected to accurately quantify the risk. Examples of denominator data include hospital admissions, catheter days, hospital days, and ventilator days. For example, if in the month of January 10 HAIs were identified and in the month of July 15 HAIs were identified, the initial conclusion would be that patients in July were more likely to develop an HAI than those in January. However, if one looked at the denominator data (1000 admissions in January, 1500 admissions in July) the conclusion would be that the incidence of HAIs in both months was identical (i.e., 1 HAI/100 hospital admissions).

Before beginning any surveillance program, it is important to identify the goals to be achieved. Goals of surveillance programs could include reducing infection rates, establishing baseline endemic rates, identifying outbreaks, persuading personnel to adopt preventive behaviors, evaluating control measures, and defending litigation. Collecting only as much data as required to achieve the goals of the surveillance program can protect the investigator from becoming buried with data and having trouble reaching any useful conclusions.

A number of surveillance measures can be readily used in veterinary practices; each has advantages and disadvantages. Some of the different surveillance programs that could be considered for use in small animal practices are passive surveillance, review of culture results, contact with clinicians and owners, daily medical record review, and environmental cultures.

Passive Surveillance

Passive surveillance is the easiest form to implement, but it tends to provide the least amount of useful data. Examples of passive surveillance include regular review of professional and discharge reports or having staff members generate a form every time an HAI is identified. The biggest limitation of passive surveillance is that it relies on staff members to accurately identify HAIs. Numerous studies in humans, as well as a study conducted in our hospital, have shown that untrained staff missed as many as 50% of the HAIs identified by infection control practitioners.

Review of Culture and Sensitivity

Routine review of culture and sensitivity results can provide a wealth of information. This surveillance method is particularly helpful in identifying epidemic outbreaks. By placing culture and sensitivity results in a spreadsheet or database, organisms with similar resistance patterns can be identified, and the possibility of an epidemic outbreak investigated. This method is also helpful for the identification of potentially important pathogens such as methicillin-resistant *Staphylococcus aureus* or vancomycin-resistant *Enterococcus*. Several commercially available programs are designed for this purpose. Some of these programs can download data directly from existing databases, whereas others require manual input.

Relying solely on culture and sensitivity results to guide infection control practices results in a gross underestimation of HAIs. In our hospital only 50% to 60% of patients that develop an HAI have an appropriate culture submitted. If we were to rely solely on these data, we would greatly underestimate the incidence of important infections such as pneumonia and surgical site infections.

Regular Contact

Regular contact with doctors or owners requires the infection control practitioner to regularly interface with the staff, owners, or both. It is superior to purely passive surveillance, but it is limited by the need of an untrained individual (the owner) to identify the presence or absence of infection.

Daily Medical Record Review

A daily medical record review provides the most surveillance information but is the most labor intensive. It requires that every patient in the hospital be surveyed on a daily basis. This approach can be used successfully to establish baseline endemic infection rates. Information gained can then be used to guide future infection control decisions.

Environmental Cultures

Historically a large amount of time and money was spent on *environmental cultures*. Now that there is a greater understanding of HAIs, the role of environmental cultures in surveillance programs has been greatly reduced, and routine environmental cultures are no longer recommended. Generally the only time an environmental culture should be considered is in the presence of an outbreak that could be environmental in origin. Endemic infections almost never have an environmental reservoir.

Reducing Hospital-Acquired Infection by Hand Washing

There is significant evidence, dating back to Ignaz Semmelweis in 1847, that hand washing reduces the incidence of HAIs. More recently it has been shown that alcohol-based antiseptics are superior to soap and water. Perhaps the most amazing fact is that compliance with hand washing in human hospitals generally ranges from 30% to 50%. The use of antiseptic hand wash is the single intervention most likely to reduce the incidence of HAIs. For hand washing to be most effective, hands should be disinfected immediately before and after patient contact *and* before any contact with other patients or the environment.

A single patient interaction may require a caregiver to wash his or her hands multiple times.

Convincing people about the importance of hand washing and then training them so that hand washing becomes second nature are difficult. A first step in achieving hand washing compliance involves selecting the hand cleaning product(s) that will be made available to clinical staff. Numerous products are Food and Drug Administration–approved for this purpose. At Tuft's University, we have found an alcohol-based hand foam to be the most readily accepted. The second step in achieving compliance is making hand antisepsis convenient. Dispensers should be placed in as many locations as possible. Finally, a staff education program should be implemented. Education can be made more effective if there is a reward for changing behavior. This can be anything from a party for the department with the highest compliance to individual rewards (i.e., movie tickets) randomly distributed when an individual is observed following proper hand antisepsis. An educational campaign is not a one-time event. Without continued reminders, staff behavior will deteriorate. Thus ongoing educational campaigns should be implemented.

Recommendations for Specific Infection Types

Most HAIs fall into one of the following categories: (1) pneumonia, (2) surgical site infections (SSIs), (3) catheter-related infections (CRIs), and (4) urinary tract infections (UTIs). Since these four categories represent the vast majority of HAIs, most measures are focused on preventing these infections. As discussed previously, the most important step in preventing HAIs is the prevention of colonization.

Pneumonia

Pneumonia is not the most common HAI in veterinary patients, but it causes greater morbidity and mortality than other HAIs. Risk factors for the development of pneumonia in veterinary patients are not well studied. In humans numerous potential risk factors have been identified, including endotracheal intubation, positive-pressure ventilation, neurologic injury/surgery, use of H₂ blockers, nasogastric tube placement, propofol use, and sedation. Many of these risk factors create breaches in defense mechanisms that normally prevent aspiration of potentially infectious material or allow bacterial colonization of sites not normally colonized (e.g., the stomach with increases in pH brought about by treatment with H₂ blockers). Such breaches, especially when combined with colonization of the oropharynx by pathogenic bacteria, greatly increase the risk of gross or microaspiration, either of which can lead to the development of pneumonia.

Surgical Site Infections

SSIs are probably the best studied of the veterinary HAIs. Duration of anesthesia, degree of wound contamination, surgical technique, and appropriate antimicrobial prophylaxis, either alone or in combination, represent the most significant risk factors. Length of anesthesia greater than 90 to 120 minutes is associated with significantly higher SSI rates.

Appropriate antimicrobial prophylaxis is essential to prevent SSIs and involves administration of antibiotics so

that blood levels are at their peak at the time of the first incision. For example, if cefazolin is used for SSI prophylaxis, it should be given no more than 1 hour and no less than 15 minutes before the start of surgery (not anesthesia) and be redosed every 2 hours. Continuation of prophylaxis for more than 24 hours in wounds that are not infected is not associated with a lower rate of SSIs.

One of the most effective controls of SSIs in humans is using prospective surveillance to determine the rate of SSIs for the surgery department as a whole and reporting individual surgeon SSI rates to each surgeon. This necessitates a high degree of confidentiality since each surgeon should be supplied with his or her SSI rate, as well the SSI rate of the department, without being informed of other surgeons' SSI rates. This approach is thought to encourage self-policing by the surgical staff and should not be viewed as a witch hunt. It should be remembered that the surgeon who routinely fixes open fractures will have a higher SSI rate than one who does mainly spays and neuters.

Catheter-Related Infections

CRIs are thought to occur most frequently from contamination of the catheter at the time of placement. They may also occur because of migration of bacteria along the catheter or from contamination of the catheter tip by systemic bacteremia. It has been my experience that most CRIs represent simple vasculitis in the area of the skin/catheter interface and that the vast majority of these cases resolve spontaneously on catheter removal. True catheter-related bloodstream infections are thought to be rare in veterinary medicine. Prevention of CRIs should focus on appropriate catheter placement and maintenance. Unfortunately there is little research into the best way to place and manage intravenous catheters in veterinary patients.

Urinary Tract Infections

UTI are the most common HAIs in both animals and humans but are associated with the least morbidity and mortality. It is important to distinguish between colonization and contamination when making the diagnosis of UTI. Intermittent catheterization has been shown to be superior to use of indwelling catheters in humans, but no studies have examined this approach in veterinary patients. Control of UTIs should focus on minimizing urinary catheter use and adhering to sterile technique during placement and maintenance. Antimicrobial prophylaxis does not prevent the development of UTIs but rather guarantees that the infection will be resistant to the antimicrobial used and thus should be avoided. In general culturing the urinary catheter tip is not recommended since positive growth frequently represents catheter colonization rather than true infection.

TREATMENT OF HOSPITAL-ACQUIRED INFECTIONS

The clinical importance of many HAIs, particularly those seen in ICU patients, is multidrug resistance. The most likely pathogens and their antibiogram vary between hospitals. It is important to have an understanding of the likely pathogens in an individual hospital since early, appropriate therapy is the key for a successful outcome.

CHAPTER 266

Rational Empiric Antimicrobial Therapy

PATRICIA M. DOWLING, Saskatoon, Saskatchewan, Canada

Concerns regarding bacterial resistance to antimicrobials are increasing the awareness of rational use in human and veterinary medicine. Effective empiric antimicrobial therapy requires matching the likely pathogen(s) to the antimicrobial drugs that should have sufficient activity against them (Table 266-1). A successful empiric antimicrobial dosage regimen depends on both a measure of drug exposure (pharmacokinetics [PK]) and a measure of the potency of the drug against the infecting organism (pharmacodynamics [PD]). New information is rapidly emerging regarding the PK/PD relationships that determine antimicrobial efficacy in both human and veterinary patients. The PK parameters used in drug dosage design are the area under the plasma concentration versus time curve (AUC) from 0 to 24 hours, the maximum plasma concentration (C_{max}), and the time the antimicrobial concentration exceeds a defined PD threshold (T). The most commonly used PD parameter is the bacterial minimum inhibitory concentration (MIC). In relating the PK and PD parameters to clinical efficacy, antimicrobial drug action is classified as either concentration dependent or time dependent.

CONCENTRATION-DEPENDENT ANTIMICROBIALS

For concentration-dependent antimicrobials, high plasma concentrations relative to the MIC of the pathogen (C_{max}:MIC) and the area under the plasma concentration–time curve that is above the bacterial MIC during the dosage

interval (area under the inhibitory curve [AUC_{0–24hr}:MIC]) are the major determinants of clinical efficacy. These drugs also have prolonged postantibiotic effects, thereby allowing once-a-day dosing while maintaining maximum clinical efficacy. For fluoroquinolones (enrofloxacin, orbifloxacin, difloxacin, marbofloxacin), clinical efficacy is associated with achieving either an AUC_{0–24hr}:MIC >125 or a C_{max}:MIC >10. For aminoglycosides (gentamicin, amikacin), achieving a C_{max}:MIC >10 is considered optimal for efficacy. Other antimicrobials that appear to have concentration-dependent activity include metronidazole (C_{max}:MIC >10 to 25) and azithromycin (AUC_{0–24hr}:MIC >25). For some pathogens such as *Pseudomonas aeruginosa*, achieving the optimum PK/PD ratios may be impossible with label or even higher-than-label dosages. In such cases underdosing is not only ineffective and but contributes to antimicrobial resistance.

TIME-DEPENDENT ANTIMICROBIALS

For time-dependent antimicrobials the time during which the antimicrobial concentration exceeds the MIC of the pathogen determines clinical efficacy (T>MIC). How much above the MIC and for what percentage of the dosing interval concentrations should be above the MIC is still debated and is likely specific for individual bacteria-drug combinations. Typically, exceeding the MIC by one to five multiples for between 40% and 100% of the dosage interval is appropriate for time-dependent bactericidal

Table 266-1

Suggested First-Choice Antimicrobials Based on the Site of Infection

Site of Infection	First-Choice Antimicrobials
Urinary tract	Amoxicillin/ampicillin Amoxicillin/clavulanic acid Cephalexin/cefadroxil Nitrofurantoin Tetracycline/doxycycline
Pyoderma	Cephalexin/cefadroxil Amoxicillin/clavulanic acid Cloxacillin/dicloxacillin/oxacillin Clindamycin/lincomycin/erythromycin
Upper respiratory tract	Amoxicillin/clavulanic acid Azithromycin Doxycycline
Lower respiratory tract	Amoxicillin/clavulanic acid ± fluoroquinolone* or aminoglycoside† Cephalosporin ± fluoroquinolone* or aminoglycoside† Clindamycin ± fluoroquinolone* Chloramphenicol Tetracycline/doxycycline Azithromycin
Surgical prophylaxis	Potassium penicillin G Cefazolin
Musculoskeletal	Cephalosporin
Septic arthritis, tenosynovitis, osteomyelitis	Clindamycin Amoxicillin/clavulanic acid Fluoroquinolone* Aminoglycoside†
Septicemia/bacteremia	Cephalosporin Cephalosporin/penicillin + enrofloxacin Cephalosporin/penicillin + aminoglycosides† Cefoxitin

*Fluoroquinolones include enrofloxacin, difloxacin, orbifloxacin, and marbofloxacin.

†Aminoglycosides include amikacin and gentamicin. In orthopedic infections these drugs can be used in local therapy to avoid toxicity.

antimicrobials. The $T > MIC$ should be closer to 100% for bacteriostatic antimicrobials and for patients that are immunosuppressed; thus these drugs typically require frequent dosing or constant-rate infusions for appropriate therapy. In sequestered infections penetration of the antimicrobial to the site of infection may require high plasma concentrations to achieve a sufficient concentration gradient. In such cases the $AUC_{0-24hr}:MIC$ and/or $C_{max}:MIC$ may also be important in determining efficacy of otherwise time-dependent antimicrobials. The penicillins, cephalosporins, most macrolides and lincosamides, tetracyclines, chloramphenicol, and the potentiated sulfonamides are considered time-dependent antimicrobials.

GUIDELINES FOR SPECIFIC TISSUES

Urinary Tract Infections

Bacterial urinary tract infection (UTI) results from normal skin and gastrointestinal tract flora ascending the urinary tract and overcoming the normal urinary tract

defenses that prevent colonization. Large retrospective studies have documented the most common uropathogens in dogs and cats, with *Escherichia coli* representing the single most common isolate from both acute and recurrent UTIs. Gram stain and pH of a urine sample help direct empiric antimicrobial therapy. If the urine is persistently alkaline, suspect a urease-producing pathogen such as *Staphylococcus* spp. if gram-positive cocci are seen or *Proteus* spp. if gram-negative rods are seen. If the urine is acidic, the most likely pathogens are *E. coli* if gram-negative rods are seen and *Enterococcus* spp. if gram-positive cocci are seen. Initial treatment of uncomplicated UTIs is straightforward since most antimicrobials undergo renal elimination to a great extent; thus urine concentrations may be up to 100 times peak plasma concentrations. All of the first-choice treatments are time-dependent antimicrobials; thus frequent dosing is important for efficacy. Amoxicillin or ampicillin has excellent activity against staphylococci, streptococci, enterococci, and *Proteus* spp. and may achieve high enough urinary concentrations to be effective against *E. coli* and *Klebsiella* spp. if dosed frequently. Amoxicillin/clavulanic acid has excellent bactericidal activity against β -lactamase-producing staphylococci, *E. coli*, and *Klebsiella* spp. However, clavulanic acid undergoes some hepatic metabolism and excretion; thus the efficacy of amoxicillin/clavulanic acid may be caused primarily by high concentrations of amoxicillin achieved in urine.

First-generation cephalosporins such as cephalexin or cefadroxil have greater stability to β -lactamases than penicillins and thus have greater activity against staphylococci and gram-negative bacteria. They have excellent activity against staphylococci, streptococci, *E. coli*, *Proteus* spp., and *Klebsiella* spp. *Pseudomonas* spp., enterococci, and *Enterobacter* spp. are resistant; and the use of cephalosporins predisposes patients to nosocomial enterococcal infections. Nitrofurantoin is an old antimicrobial still used in human medicine only for UTIs since therapeutic concentrations are not attained in plasma or tissues. It is a good first-line treatment for UTIs caused by *E. coli*, enterococci, staphylococci, *Klebsiella* spp., and *Enterobacter* spp.; but it must be dosed every 8 hours, making client compliance difficult.

Tetracyclines are broad-spectrum antimicrobials; but, because of plasmid-mediated resistance, staphylococci, enterococci, *Enterobacter* spp., *E. coli*, *Klebsiella* spp., and *Proteus* spp. have variable susceptibility. However, the tetracyclines are excreted unchanged in the urine; thus high urinary concentrations may result in therapeutic efficacy despite susceptibility test results that indicate resistance. Doxycycline is a very lipid soluble tetracycline that is better tolerated in cats and achieves therapeutic concentrations in the prostatic and renal tissues. Because of biliary elimination, doxycycline was thought not to be useful for uncomplicated UTIs, but a recent study demonstrated that effective concentrations are achieved in the urine of dogs and cats (Wilson et al., 2006). The combinations of trimethoprim or ormetoprim with a sulfonamide are synergistic and bactericidal against staphylococci, streptococci, *E. coli*, and *Proteus* spp. Activity against enterococci and *Klebsiella* spp. is

variable, and *Pseudomonas* spp. are resistant. Although their spectrum of activity makes the potentiated sulfonamides rational first-line treatment choices, they are associated with a number of side effects that discourage more frequent selection.

Enrofloxacin, orbifloxacin, difloxacin, and marbofloxacin are all fluoroquinolones approved for UTIs in the dog, and some are approved in the cat, but all are used in cats. All fluoroquinolones have excellent activity against staphylococci and gram-negative bacteria but have variable activity against streptococci and enterococci. They are the only orally administered antimicrobials with efficacy against *Pseudomonas* spp. The therapeutic advantage of these drugs is their gram-negative antimicrobial activity, their excellent penetration into the prostate gland, and their activity in infected tissues; their concentration-dependent killing allows for once-a-day dosing. However, it is inappropriate to use these important antimicrobials as first-line treatment of uncomplicated UTIs. Their use should be reserved for complicated UTIs such as cases of pyelonephritis that involve gram-negative bacteria and for UTIs in intact male dogs in which prostatic involvement is likely.

Pyoderma

Pyoderma is a common bacterial skin disease of dogs caused by *Staphylococcus intermedius*. *S. intermedius* is normal skin flora and colonizes the upper respiratory tract, the oral cavity, the anal region, and the external ear canal. Most canine staphylococci produce slime that allows the bacteria to adhere to cells; and they contain protein A, which activates the complement cascade and incites inflammation. *E. coli*, *Proteus* spp., and *Pseudomonas* spp. can transiently colonize the skin and occasionally may become involved in pyoderma secondary to the staphylococcal infection. Treatment of the primary staphylococcal infection is usually sufficient to resolve these secondary infections.

Effective treatment of pyoderma requires systemically administered antimicrobials and topically applied antibacterial agents, along with specific treatment of any underlying causes. Appropriate empiric antimicrobials must be resistant to β -lactamase produced by staphylococci. *S. intermedius* typically does not demonstrate antimicrobial resistance because it does not readily retain antimicrobial resistance plasmids. Resistance patterns are predictable when there has been no prior antimicrobial exposure. First-generation cephalosporins such as cephalexin or cefadroxil are the usual first-line treatment choices for staphylococcal pyoderma. Dosage regimens that target $T > MIC$ for 40% to 50% of the dosing interval are efficacious. Cefpodoxime proxetil, a third-generation cephalosporin, is attractive for use because of its once-daily dosing schedule but should be reserved for infections more serious than superficial pyoderma. The antistaphylococcal penicillins (cloxacillin, dicloxacillin, and oxacillin) are excellent for first-choice therapy of pyoderma. However, because of their limited spectrum of activity, these drugs are not usually on stock in a veterinary clinic, but they can be prescribed easily from a human pharmacy. Because of poor oral bioavailability and rapid renal elimination, they

must be dosed every 6 hours, making client compliance difficult. The macrolides and lincosamides are reasonable choices for first-time treatment of pyoderma, but recurrent infections are likely to be resistant. Erythromycin is associated with a high incidence of gastrointestinal upset in dogs. This can be avoided by using enteric-coated tablets, administering with food, prescribing antiemetics for the first 2 to 3 days of therapy, and initiating therapy with a lower dose. This treatment regimen is too complicated and inconvenient for most clients, and most clinicians prefer to use antimicrobials that do not routinely induce vomiting. Lincomycin has the same activity as erythromycin and does not cause gastrointestinal upset. Clindamycin is very active against *Staphylococcus* spp. and anaerobic bacteria. It distributes well into tissues and is active in purulent material. Trimethoprim or ormetoprim combined with a sulfonamide are effective in most cases of superficial pyoderma, but the risks of adverse effects such as keratoconjunctivitis sicca and polysystemic drug reactions limit their use.

Mupirocin is a topical therapy for localized pyoderma. It has excellent activity against gram-positive cocci, is not absorbed systemically, and is chemically unrelated to other antimicrobials. It is well tolerated in cats for the treatment of feline acne. Mupirocin ointment penetrates well into granulomatous lesions such as interdigital abscesses. Owners can decrease the relapse rate and severity of recurrent pyoderma if they immediately apply mupirocin every 12 hours when they first notice early lesions developing.

For most cases of pyoderma 3 to 6 weeks of therapy are required for a clinical cure; and some dogs require chronic low-dose or pulse-dose therapy with amoxicillin/clavulanic acid, cloxacillin, or a cephalosporin for control of recurrent pyodermas. Enrofloxacin, difloxacin, marbofloxacin, and orbifloxacin are first choices only for antimicrobial therapy of deep pyodermas and short-term therapy of recurrent pyoderma when resistance has developed. They have excellent activity against *S. intermedius*, *Pseudomonas* spp., and *Proteus* spp., the organisms most likely to be involved in refractory cases. Fluoroquinolones have ideal pharmacokinetic properties; they accumulate in leukocytes and retain activity in necrotic and purulent debris. Since they are concentration-dependent killers, high-dose once-daily administration is ideal and increases client compliance with the treatment regimen. Fluoroquinolone therapy should be avoided for chronic low-dose or pulse-dose therapy because chromosomal-mediated resistance occurs with chronic exposure.

Respiratory Tract Infections

Upper Respiratory Tract

Primary bacterial infection of the upper respiratory tract is uncommon, but almost all dogs and cats with a mucopurulent or purulent nasal discharge have some bacterial component to their disease. *Bordetella bronchiseptica* can cause primary upper respiratory tract (URT) infections in dogs; whereas *B. bronchiseptica*, *Mycoplasma* spp., and *Chlamydia felis* cause primary URT infections in the cat. Most cases of bacterial rhinitis are secondary to

other diseases and caused by the variety of normal flora found in the nasal passages; culture and susceptibility test results are difficult to interpret. Treating the bacterial infection without correcting the underlying cause is very unrewarding and encourages emergence of antimicrobial-resistant pathogens such as *P. aeruginosa*. Chronic URT infection may lead to sinus osteomyelitis. Empiric therapy for URT infections in dogs and cats includes amoxicillin/clavulanate, cephalexin or cefadroxil, or drugs with efficacy against *Mycoplasma* spp. and *C. felis* such as doxycycline, azithromycin, or a fluoroquinolone. Doxycycline is considered the most effective therapy for chlamydiosis, but clinical signs improve with any of these therapies, and cats frequently remain polymerase chain reaction or immunofluorescent antibody test positive. Doxycycline is often avoided in young animals because of fears of causing dental damage. Even in children, doxycycline is the least likely of the tetracyclines to cause dental damage, and there are no published reports of dental abnormalities from the use of doxycycline in puppies and kittens. However, oral administration to cats is associated with esophageal damage that can lead to stricture; thus administration of tablets or capsules should be followed with food or water to ensure passage into the stomach. Fluoroquinolones should be reserved for serious infections based on culture and susceptibility testing. Enrofloxacin should be avoided in cats because of the potential for retinal damage. Tetracycline, chloramphenicol, or erythromycin ophthalmic ointments can be used to treat concurrent conjunctivitis. With chronic infections in dogs or cats, drugs that penetrate bone and target anaerobic bacteria such as amoxicillin/clavulanic acid, clindamycin, or cephalexin or cefadroxil should be chosen.

Lower Respiratory Tract

Bacterial pneumonia in dogs and cats is usually secondary to some pathologic process that disrupts normal pulmonary defence mechanisms. Treatment choices are dictated by the specific etiology and the clinical status of the patient. In dogs with community-acquired bacterial infections the likely causative pathogens are *B. bronchiseptica*, *Mycoplasma* spp., *Streptococcus zooepidemicus*, *Pasteurella* spp., and *E. coli*. In cats the pathogens are similar, with the addition of *C. felis*. In previously ill animals or animals with hospital-acquired illness, *E. coli*, *Klebsiella* spp., *Pasteurella* spp., streptococci, staphylococci, anaerobes, *B. bronchiseptica*, *Pseudomonas* spp., and *Mycoplasma* spp. are frequently involved; and more than one bacterial pathogen is commonly isolated. The unpredictable antimicrobial susceptibility of *E. coli* and other gram-negative bacteria makes it difficult to choose antimicrobial therapy without susceptibility testing, thus sampling the lower respiratory tract for culture and sensitivity and cytology is strongly recommended. The critically ill patient should be started on a broad-spectrum, parenteral antimicrobial regimen as soon as possible until results of definitive cultures are obtained. Gram-negative rods frequently are susceptible to potentiated sulfonamides, gentamicin, chloramphenicol, cefpodoxime proxetil,

and the fluoroquinolones (enrofloxacin, orbifloxacin, difloxacin, marbofloxacin). *B. bronchiseptica* typically is susceptible to amoxicillin-clavulanic acid, tetracyclines, or azithromycin; but some isolates are resistant to the fluoroquinolones. Gram-positive cocci are frequently susceptible to amoxicillin/clavulanic acid, chloramphenicol, cephalosporins, or azithromycin. Aminoglycosides or enrofloxacin can be administered concurrently with parenteral formulations of penicillins or cephalosporins for broad-spectrum treatment of seriously ill patients. Clindamycin or metronidazole can be added to provide activity against β -lactamase-producing *Bacteroides fragilis*.

Musculoskeletal Infections

Prophylactic Antimicrobials

Veterinary surgeons routinely use prophylactic antimicrobials in surgical patients undergoing orthopedic procedures, but little evidence from clinical trials demonstrates the efficacy of this practice. In humans undergoing clean bone surgery, antimicrobials are administered intravenously from 30 minutes before skin incision to no longer than 24 hours after the operation. Cefazolin typically is the prophylactic antimicrobial therapy of choice in small animal practice. However, in the only published veterinary trial of prophylactic antimicrobial therapy in dogs undergoing elective orthopedic surgery, prophylaxis decreased the postoperative infection rate, but potassium penicillin G was as efficacious as cefazolin (Whittem et al., 1999). Prophylactic antimicrobial therapy should be followed by close observation and treatment with appropriate antimicrobials and surgery if postoperative infection is diagnosed.

Septic Arthritis, Tenosynovitis, Osteomyelitis

Because of the variety of pathogens involved in musculoskeletal infections, appropriate samples must be submitted for culture and susceptibility testing. Aggressive antimicrobial therapy should be initiated as soon as there is sufficient evidence of infection because of the devastating consequences of bone, joint, or tendon sheath infections. While awaiting culture results, initial antimicrobial selection can be chosen based on clinical case characteristics. In adult dogs and cats, septic arthritis and tenosynovitis commonly result from wounds or iatrogenic contamination with bacteria. In wounds a variety of gram-positive and gram-negative bacteria typically are present, whereas *Staphylococcus aureus* and *S. intermedius* are the usual isolates from iatrogenic infections, with methicillin-resistant *S. aureus* increasingly reported from veterinary cases. Osteomyelitis in dogs and cats is most commonly caused by *S. intermedius*. Polymicrobial infections are common in small animals and may include mixtures of streptococci, enterococci, Enterobacteriaceae (*E. coli*, *Klebsiella* spp., *Pseudomonas* spp.) and anaerobic bacteria. Cat fight abscesses typically are caused by *Pasteurella multocida*. *Pseudomonas* spp. often colonize devitalized tissues such as those occurring with "big dog-little dog" degloving injuries. For most bone and joint infections caused by β -lactamase-producing staphylococci,

cephalosporins (cefazolin, cephalixin, cefpodoxime proxetil), clindamycin, or amoxicillin-clavulanic acid are effective. Clindamycin and metronidazole are used for anaerobic infections. The aminoglycosides (amikacin, gentamicin) and fluoroquinolones (enrofloxacin, orbifloxacin, difloxacin, marbofloxacin) typically have good activity against staphylococci and excellent activity against gram-negative pathogens. Although amikacin usually has good activity against *Pseudomonas* spp., it has poor activity against streptococci compared to gentamicin. Because nephrotoxicity and ototoxicity are related to duration of treatment, the aminoglycosides are often reserved for treatment of musculoskeletal infections by local delivery techniques. The excellent broad-spectrum antimicrobial activity, good safety profiles, and availability of injectable (enrofloxacin) and oral formulations of fluoroquinolones make them popular choices for treatment of musculoskeletal infections. The newer human macrolide antimicrobials (azithromycin, clarithromycin) may also be efficacious for musculoskeletal infections and have good safety profiles in dogs and cats.

Septicemia/Bacteremia

Septicemia is common in critically ill canine and feline patients, and the majority that are septicemic have positive blood cultures for bacteria. In dogs gram-negative bacteria (especially *E. coli*) are most common, followed by gram-positive cocci and anaerobes. Polymicrobial infections are also common and usually involve gram-negative

enterics and anaerobes. Bacteria cultured from cats are primarily gram-negative enterics or anaerobes. Therefore it is common to use intravenous β -lactam/aminoglycoside or β -lactam/enrofloxacin combinations for initial therapy of septic dogs and cats. The concentration-dependent drugs are administered once daily, but the time-dependent β -lactam drugs must be administered either by constant rate infusion or at least every 6 hours. Cefoxitin is a second-generation cephalosporin with good activity against anaerobes and gram-negative enterics that can be used in septic dogs and cats. Imipenem, meropenem, and vancomycin occasionally are used to treat resistant infections in severely ill dogs and cats; but because of their importance in human medicine their use should not be routine in veterinary patients.

Rational Use of Glucocorticoids in Infectious Disease

ADAM MORDECAI, *Buffalo Grove, Illinois*

RANCE K. SELLON, *Pullman, Washington*

Evidence supporting the use of glucocorticoids in the face of infections in small animal patients is based on anecdotal or retrospective reports. Few prospective controlled studies have critically evaluated the benefits or consequences of glucocorticoid use in this setting. Frequently cited reasons for administration of glucocorticoids in treating infectious disease include suppression of harmful inflammatory or immune responses and suppression of presumed secondary immune-mediated processes. Despite the fact that there is little scientific evidence that supports their use, glucocorticoids are frequently suggested for patients with infectious disease. The aim of this chapter is to review the use of glucocorticoids for infections and to offer guidelines for their use. This chapter does not specifically address the use of glucocorticoids, either topical or systemic, in patients with ocular infections or ocular manifestations of infectious disease, although they are used frequently (see Section XII).

MECHANISM OF ACTION

The mechanisms by which glucocorticoids mediate anti-inflammatory activity are not understood completely (also see Chapter 89). Glucocorticoids first diffuse across the plasma membrane and bind to specific glucocorticoid receptors in the cytoplasm. The steroid-receptor complex then exerts a variety of effects. The complex can inactivate proinflammatory transcription factors and increase the production of proteins that inhibit cytokine production. Glucocorticoids can also mediate their actions through nontranscriptional means such as decreasing the half-life of messenger ribonucleic acid for inflammatory cytokines. Glucocorticoids attenuate inflammation by inducing lipocortin-1, which directly inhibits phospholipase A₂, an enzyme that is responsible for production of inflammatory prostaglandins, leukotrienes, and eicosanoids. Through these and other mechanisms inflammation and immune function can be altered or suppressed by glucocorticoids. Both the cellular and humoral arms of the immune system can be affected; however, the cellular response is thought to be most compromised. Poor cellular immune responses could enhance the pathogenic potential of some infectious organisms, prevent cell-mediated clearance of organisms, and perpetuate inflammation secondary to persistence of organisms and activation of other inflammatory pathways. Glucocorticoids are commonly thought to decrease phagocytic and oxidative functions of phagocytic cells in a dose-dependent manner, thereby compromising the ability to kill ingested organisms. It is

these general properties that not only support the use of glucocorticoids in patients with infectious disease but also raise concerns about the potential side effects and complications associated with their use.

GLUCOCORTICOIDS IN HUMANS WITH INFECTIOUS DISEASE

A survey of the human literature on the use of glucocorticoids as adjunctive treatment for infectious disease puts into perspective many of the uncertainties. Conclusions regarding the benefits of glucocorticoids given to humans with infectious disease vary, depending on the infectious agent studied, the age of the patient group studied, the dose and/or duration of glucocorticoid therapy, the parameters assessed (e.g., immunologic or infectious agent parameters such as cytokine levels or quantity of infectious agent detected), the presence of other infectious agents, and by extension, perhaps, of other concurrent diseases. Human immunodeficiency virus-1 imposes its own perturbations on immune and inflammatory responses. Many of the case reports either involve small numbers of patients or lack appropriate controls. To illustrate, placebo-controlled studies of children with viral respiratory infection treated with glucocorticoids found benefit when treated with several days of prednisone but no benefit in studies in which a single dose of dexamethasone was given at admission. Glucocorticoids have also been shown to be of benefit in humans with peritonsillar abscesses and to improve survival with mycobacterial meningitis, but they do not prevent postrecovery disability. Interestingly, one study of glucocorticoid treatment of humans with mycobacterial meningitis suggests that the clinical benefits may be from mechanisms other than antiinflammatory or immune modulation after finding no difference in a number of inflammatory and immunologic parameters in placebo- and glucocorticoid-treated groups. Low doses of glucocorticoids generally are accepted as beneficial in people with sepsis, whereas high doses appear to offer no benefit.

GLUCOCORTICOIDS IN SMALL ANIMALS WITH INFECTIOUS DISEASE

Respiratory Infections

It has been proposed that antiinflammatory doses of glucocorticoids for 5 to 7 days may be effective in ameliorating cough associated with uncomplicated infectious

tracheobronchitis but do not significantly shorten the clinical course of disease. It is commonly recognized that following initial administration of antifungal agents to patients with fungal pneumonia (i.e., blastomycosis and histoplasmosis) respiratory signs can worsen as a consequence of heightened inflammation associated with fungal death. Glucocorticoids are thought to prevent treatment-induced inflammation from occurring; however, as yet there are no studies showing this benefit. In a retrospective study of chronic histoplasmosis in dogs (Schulman, et al., 1999), clinical signs of coughing from airway obstruction associated with hilar lymphadenomegaly resolved more quickly when treated with immunosuppressive dosages (2 to 4 mg/kg/day) of prednisone alone or prednisone and antifungal drugs compared to those in dogs treated with antifungal chemotherapy alone (less than 3 weeks compared to approximately 9 weeks). In this study the glucocorticoid-treated dogs did not show evidence of dissemination of disease.

Central Nervous System Infections

In central nervous system (CNS) infections inflammatory mediators and toxic factors produced by the immune system may be more responsible for CNS damage than the primary pathogen. The treatment of bacterial organisms can result in their lysis and release of inflammatory cell wall components, including lipopolysaccharides and outer membrane vesicles. As yet there are no controlled studies addressing the use of glucocorticoids in dogs or cats with infectious meningitis, but anecdotal experience, case reports, and the human literature suggest a potential benefit. At our institution patients suspected to have CNS infection based on cerebral spinal fluid (CSF) pleocytosis, elevated CSF protein content, and/or consistent magnetic resonance imaging findings are treated with a broad-spectrum antiinflammatory protocol (trimethoprim sulfa, 15 mg/kg BID; clindamycin, 12.5 mg/kg BID; prednisone, 0.5 mg/kg BID) while awaiting more definitive results, including bacterial culture and viral and protozoal titers. Diagnostic testing should always be performed before any treatment since it may affect CSF analysis and culture results. In addition, glucocorticoids may attenuate the increased blood-brain barrier permeability that results from inflammation, thereby theoretically reducing antimicrobial penetration into the CSF. Clinical studies in small animals with bacterial meningitis that address antibiotic penetration in the face of glucocorticoids are lacking, and long-term consequences of glucocorticoid therapy for infectious meningitis have not been established.

Disseminated/Miscellaneous Infections

Glucocorticoids are used frequently in conjunction with antimicrobials for hemolytic anemia or thrombocytopenia while awaiting results to differentiate a primary immune-mediated hemolytic process from hemolytic disease secondary to an infectious organism such as *Babesia* spp. or *Mycoplasma* spp. Common belief holds that immune-mediated destruction contributes to anemia or thrombocytopenia with these infections and the

addition of glucocorticoids may decrease this damage, but there are no controlled studies demonstrating proof of efficacy. In one study glucocorticoid-treated dogs infected by *Rickettsia rickettsii*-induced Rocky Mountain spotted fever (RMSF) did not show evidence of dissemination of disease (Breitschwerdt, et al., 1997). Because treatment with antimicrobials for RMSF is often effective for improving clinical signs within 1 to 2 days of initiating therapy, the need to use glucocorticoids should be based on a case-by-case basis and is not recommended for routine treatment.

Of the many canine and feline infectious diseases, treatment of cats with feline infectious peritonitis (FIP) with glucocorticoids would be a logical application of the drugs, given the key role that immunopathogenesis plays in the clinical disease. Glucocorticoids are often recommended for FIP, despite clinical studies failing to demonstrate the benefits of glucocorticoids. One study has suggested the benefit of concurrent use of recombinant feline interferon and glucocorticoid administration to cats with FIP, but the report included no controls, and the diagnosis of FIP was not confirmed in all cases (Ishida, et al., 2004). Treatment of other systemic infections with glucocorticoids, including *Mycoplasma haemofelis*, and *Babesia canis*, has no support in controlled clinical studies, although glucocorticoids are commonly used in the treatment of patients infected with these organisms.

Juvenile cellulitis (puppy strangles) is a syndrome of facial swelling, lymphadenopathy, deep pyoderma of the head and face, fever, polyarthritis, anorexia, and depression. The disease is seen most often in young dogs and is attributed to immune-mediated responses to bacterial antigens. Affected patients usually respond to antimicrobials and immunosuppressive doses of glucocorticoids, and available literature provides reasonable (although not case-controlled) evidence for the use of immunosuppressive doses of glucocorticoids in the management of this disease. The disease may recur if corticosteroid therapy is tapered too quickly; thus a slower tapering protocol may be required.

Sepsis/Systemic Inflammatory Response Syndrome/Acute Respiratory Distress Syndrome/Relative Adrenal Insufficiency

Systemic inflammatory response syndrome (SIRS) is a term used to describe the clinical consequences of severe systemic inflammation. Severe systemic inflammation can result in secondary conditions such as disseminated intravascular coagulopathy, acute respiratory distress syndrome (ARDS), and multiple organ dysfunction syndrome. Dysregulated systemic inflammation is a major contributor to the morbidity and mortality in sepsis and ARDS. Relative adrenal insufficiency (RAI) is defined as a usually transient lack of response to endogenous or exogenous adrenocorticotrophic hormone (ACTH) and occurs in patients with widespread systemic inflammation (also see Chapter 50). Suspicion of RAI is often based on poor systemic pressures despite appropriate hydration (central venous pressures ranging between 5 and 10 cm of water) and vasopressor (dobutamine,

norepinephrine) dependency. RAI occurs with relative frequency in human septic SIRS patients and has been described recently in septic dogs (Burkitt, et al., 2007). Human studies have demonstrated that a short course of physiologic doses of glucocorticoids improves clinical outcomes in patients with sepsis. It is likely that future studies will show similar benefits for dogs with sepsis and RAI.

**CONSIDERATIONS FOR
GLUCOCORTICOID USE**

Prednisone and prednisolone are ideal glucocorticoids for use in patients with infectious disease because of their short duration of activity (12 to 36 hours). Prednisolone sodium succinate (Solu-Delta-Cortef, Pfizer Animal Health) or methylprednisolone sodium succinate (Solu-Medrol, Upjohn) are parenteral formulations that may be used if patients are unable to take oral formulations. Dexamethasone would be an additional alternative for these patients, but its activity is approximately 48 hours, making it perhaps a less ideal first choice. Given its long storage life and because it is relatively inexpensive compared to other glucocorticoids, practitioners may elect to use dexamethasone. Depot formulations such as methylprednisolone acetate (Depo-Medrol, Upjohn) are not recommended because of their long duration of activity.

Dosage

Systematic evaluation of glucocorticoid dosages in small animal infectious disease patients has not been performed. Typical therapeutic ranges (Table 267-1) to achieve either antiinflammatory or immunosuppressive effects have been suggested. Ideally therapy with glucocorticoids should be initiated at the lowest doses needed to obtain the desired clinical response. Clinicians should be aware of the relative potencies of the commonly used glucocorticoids (Table 267-2) when selecting a glucocorticoid and dose.

Duration of Glucocorticoid Treatment

If the correct underlying cause has been identified and antiinfective treatment is effective, clinical improvement usually occurs within days. It is our recommendation that concurrent glucocorticoid therapy should last only as long as needed to achieve and maintain the desired clinical response—in some patients that period may be days, in others weeks. The decision to stop glucocorticoid therapy

depends on the patient's clinical status, clinician preference, and potential for clinical relapse or deterioration.

Common belief holds that glucocorticoid tapering is needed to prevent signs of iatrogenic hypoadrenocorticism. It is our view that tapering is better suited to identify early relapse or recurrence of the syndrome requiring glucocorticoid therapy. If the need arises to acutely stop glucocorticoids, theoretically a clinician should immediately be able to reduce the amount given to a physiologic dose and prevent clinical signs associated with iatrogenic hypoadrenocorticism. Our argument is based on the fact that dogs with glucocorticoid deficiency from spontaneous hypoadrenocorticism fare well with prednisone given at physiologic or slightly higher doses (0.2 to 0.4 mg/kg/day). If the reduction in dose is well tolerated, a brief period of alternate-day therapy should allow return of normal adrenal function. The time period for return of normal adrenal function depends on many variables, including dose, formulation, duration of therapy, and variation in patient response preventing any absolute recommendations. In general, longer durations of therapy with higher doses or use of formulations with greater duration of activity may require a longer period of dose reduction for return of normal adrenal function. Periodic testing in the form of drug cessation trials or ACTH stimulation may be required if iatrogenic hypoadrenocorticism is suspected. A period of dose reduction should also be considered when treating patients concurrently with glucocorticoids and ketoconazole for systemic fungal infections since ketoconazole impairs adrenal glucocorticoid synthesis and could lead to transient iatrogenic hypoadrenocorticism.

**Adverse Effects of Glucocorticoids
With Infectious Disease**

Apart from the usual side effects of glucocorticoids, there is virtually no information on small animal patients that addresses adverse effects of glucocorticoids when given concurrently with antiinfective therapy. The potential for immunosuppression and exacerbation of existing infection or development of additional infections is a valid concern, yet it seldom seems to be recognized clinically. Perhaps it is more important that the clinician not be lulled into a false sense of security regarding apparent positive responses in patients with infections also treated with glucocorticoids. A patient could improve initially because of antiinflammatory properties and yet worsen with time because of decreased immunologic clearance of infectious organisms and progressive infection, particularly if antiinfective therapy is ineffective. Theoretically

Table 267-1

Glucocorticoid Dosing Recommendations (mg/kg/day)

Glucocorticoid	Physiologic Replacement	Antiinflammatory	Immune Suppression
Hydrocortisone	0.5-1.0	2.5-5	Not used
Prednisone	0.1-0.2	0.5-1	2-4 (dog); 4-8 (cat)
Dexamethasone	0.02-0.04	0.1-0.2	0.4-0.8

Table 267-2

Relative Glucocorticoid Potency of Formulations Likely To Be Used in Patients With Infectious Disease

Glucocorticoid	Potency Relative to Hydrocortisone
Hydrocortisone	1
Prednisone/prednisolone	5
Dexamethasone	25

supraphysiologic doses of glucocorticoids could inhibit the inflammation that is necessary for wound repair and retard healing. When adverse effects are suspected secondary to immunosuppression (worsening of disease), rapid reduction of glucocorticoid doses as suggested previously may be required.

The etiologic agents of some infections such as endocarditis may be hard to confirm despite appropriate testing (blood cultures, urine cultures). Treatment with glucocorticoids may increase the chance of recovery of an organism such as *Bartonella* (Dr. Ed Breitschwerdt, personal communication) but glucocorticoids are not advised for that specific intent.

GUIDELINES FOR USE OF GLUCOCORTICOID WITH INFECTIONS

We believe that some patients with infections benefit from treatment with antiinflammatory or occasionally higher doses of glucocorticoids. We suspect that this view is held by many other clinicians despite the absence of rigorous evaluation of glucocorticoid use in small animal infections. When using glucocorticoids in patients with infectious disease, whenever possible we try to adhere to the following guidelines:

- Diagnostic studies to identify the specific cause of infection should be completed before the administration of glucocorticoids.
- Glucocorticoid treatment should be implemented after or at the same time as antiinfective therapy.
- The decision to administer glucocorticoids to patients with an infection should be made on a case-by-case basis that weighs the patient's clinical status and relative benefits against the potential risks of complications and adverse effects.
- Glucocorticoid administration should not form a blanket approach to treatment of a given infectious agent.
- Doses of glucocorticoids should be appropriate for the goal of therapy (e.g., antiinflammatory, immunosuppressive, or physiologic replacement for patients with RAI).

- Administration of glucocorticoids with short or intermediate duration of activity (e.g., prednisone) is preferred to glucocorticoids with longer durations of antiinflammatory or immunosuppressive activity; depot forms of glucocorticoids are not advised.
- Glucocorticoids should be administered at the lowest dosages and for no longer than needed to achieve and maintain desired clinical responses.
- Patients treated with glucocorticoids should be assessed regularly and carefully for complications of therapy, particularly progressive infection. Because glucocorticoid administration can attenuate the very patient responses that alert clinicians to the existence of problems (e.g., fever, pain) that could otherwise suggest clinical deterioration in patients not receiving glucocorticoids, enhanced attention is warranted.
- In some patients receiving glucocorticoids concurrently with antiinfective therapy (e.g., those with systemic fungal infections), the duration of the antiinfective treatment period should be extended.
- Owners should be advised of the potential risks associated with a treatment approach (glucocorticoids for infection) that lacks support of appropriately performed clinical studies.

In summary, predominately anecdotal evidence supports the administration of glucocorticoids to some dogs and cats with infectious disease. Definitive studies that examine the benefits or complications of its use are needed to better characterize the indications and contraindications to the administration of glucocorticoids to such patients.

Canine Brucellosis

AUTUMN P. DAVIDSON, *Davis, California*

Brucellosis is the primary contagious infectious venereal disease of concern in canine reproduction. *Brucella canis* causes reproductive failure in both the male and female dog. Screening for *B. canis* is an important part of the prebreeding evaluation of any dog and should be included in the initial diagnostic approach to any case of canine abortion or apparent infertility. Because the incidence of canine brucellosis is low in many parts of the country, breeder compliance with regular testing can wane, making continued veterinary vigilance important.

ETIOLOGY AND MICROBIOLOGY

Canine brucellosis is caused by *B. canis*, a small, gram-negative, nonspore forming aerobic coccobacillus. *Brucella abortus*, *Brucella melitensis*, and *Brucella suis* have occasionally caused canine infections but are comparatively very rare. Transmission occurs through direct exposure to bodily fluids (semen, lochia, aborted fetuses/placentas, milk, and less commonly urine containing semen) containing an infectious dose of organism. A large amount of organism is shed in the vulvar discharge of bitches 4 to 6 weeks after abortion. The highest concentration of organism is shed in the semen of infected dogs 2 to 3 months after infection, with lesser amounts shed for years. Urine can serve as a contaminated vehicle because of the proximity of the urinary and genital tracts in the dog. Milk also can serve as a vehicle for shedding. Therefore transmission is primarily venereal and oral (i.e., through the mucous membranes); the latter is associated with the ingestion of infectious materials. Urine and indirect mucous membrane contact are not important routes of transmission. The aerosol route is only important if kennel conditions are very crowded. *B. canis* is short lived outside the dog and is readily inactivated by common disinfectants such as 1% sodium hypochlorite, 70% ethanol, iodine/alcohol solutions, glutaraldehyde, and formaldehyde.

Brucella organisms attach to and penetrate the mucous membranes; virulence is proportional to the infectious dose. After replication in regional lymph nodes, bacteremia occurs within 7 to 30 days after exposure with subsequent transportation to monocyte/macrophage series cells, prostate, uterus, and placenta; *B. canis* has a predilection for steroid-dependent (reproductive) tissues. It survives facultatively within monocytes and macrophages. *Brucella* organisms are able to survive and multiply in monocyte/macrophage cells because they inhibit the bactericidal myeloperoxidase-peroxide-halide system by releasing 5'-guanosine and adenine. Early in infection polymorphonuclear cells and macrophages are relatively ineffectual in killing *B. canis* intracellularly.

Brucella organisms can be identified in the rough endoplasmic reticulum of placental trophoblastic giant cells in an infected bitch's gravid uterus. Severe necrotizing placentitis with infarction of the labyrinth region, coagulation necrosis of the chorionic villi, and necrotizing arteritis result in fetal death. The organism can be found in the gastric contents of the aborted fetuses. Necrotizing vasculitis causing granulomatous lesions results in epididymal and subsequent testicular and prostatic pathology.

EPIZOOTIOLOGY

Members of the Canidae family are the natural hosts of *B. canis*; and any mature, reproductively active breed of dog is susceptible to infection. Canine brucellosis occurs most commonly as an outbreak in a large commercial kennel and less commonly in privately owned dogs. Outbreaks of canine brucellosis traditionally have geographic orientation, with increased incidence seen in the southernmost states of the United States and more commonly in Mexico, Central and South America, The People's Republic of China, and Japan. The incidence in Europe has been low. The increased practice and success of canine semen processing for exportation (chilling and cryopreservation) for the purpose of artificial insemination now makes canine brucellosis a concern worldwide since direct mucosal contact among dogs is no longer necessary for transmission.

Humans can become infected with *B. canis*, although apparently rarely. Approximately 40 cases of human infection have been reported in several countries; however, the actual number is unknown since human cases are rarely diagnosed or, if diagnosed, reported. Transmission to humans most commonly occurs through contact with semen from an infected dog, vulvar discharge from an infected bitch, aborted fetuses or placentas, or direct accidental laboratory exposure.

CLINICAL SIGNS

Canine brucellosis has high morbidity but low mortality. The clinical systemic signs are often subtle and can include suboptimal athletic performance, lumbar pain, lameness, weight loss, and lethargy.

The primary clinical sign of brucellosis in the bitch is pregnancy loss, which can occur early (day 20) in gestation, resulting in fetal resorption, or more commonly (approximately 75% of cases) later in gestation (generally 45 to 59 days), resulting in abortion. Bitches with pregnancy loss early in gestation can appear to be infertile unless early ultrasonographic pregnancy evaluation

is performed. Nongravid bitches can be asymptomatic or can show regional lymphadenopathy (pharyngeal if orally acquired, inguinal and pelvic if venereally acquired).

The primary acute clinical signs of brucellosis in the male dog reflect disease of the portions of the reproductive tract participating in the maturation, transport, and storage of spermatozoa. Epididymitis is common, with associated orchitis, scrotal dermatitis, and resultant deterioration of semen quality and fertility. Chronically testicular atrophy and infertility can occur. The organism can be found in the prostate gland and urine. Antisperm antibodies develop in association with brucellosis-induced epididymal granulomas and further contribute to infertility. Diminished sperm counts (oligospermia), poor sperm motility (asthenospermia), and increased morphologic abnormalities (teratospermia) are characteristic of semen in a *Brucella*-infected dog. Detached sperm heads, proximal and distal cytoplasmic droplets, and acrosomal deformities are the most common morphologic abnormalities. Sperm head-to-head agglutination suggests the presence of antisperm antibodies. Pyospermia develops 3 to 4 months after infection. An absence of sperm in the ejaculate (azoospermia) can also result.

Chronic infections in either sex can result in uveitis, granulomatous splenitis, discospondylitis, granulomatous dermatitis, meningoencephalitis, and nephritis. Bacteremia can persist for years, and asymptomatic dogs can remain infectious for long intervals.

Spontaneous recovery can occur 1 to 5 years after infection but is difficult to document. Bitches can produce normal litters subsequent to multiple abortions but can remain infectious to their offspring. Dogs may remain infertile because of irreparable damage to the spermatogenic apparatus.

DIAGNOSIS

Serology, blood or tissue culture, histopathology, and polymerase chain reaction (PCR) techniques are appropriate for the diagnosis of canine brucellosis. Common screening serologic tests include the rapid slide agglutination test (RSAT), which uses *B. ovis* as the antigen; the semiquantitative 2-mercaptoethanol modified RSAT, which substitutes *B. canis* as the antigen for increased (but not perfect) specificity; the semiquantitative tube agglutination test, in which a titer of 1:200 or greater correlates well with positive blood culture; the indirect fluorescent antibody; the cell wall agar gel immunodiffusion (AGIDcwa); the cytoplasmic agar gel immunodiffusion (AGIDcpa); and the enzyme-linked immunosorbent assay. AGID testing requires trained personnel and special media. Positive serologic results are detected in most dogs within 8 to 12 weeks of infection. Because incubation periods can vary from 2 to 12 weeks, there can be a window of time in which an infected individual may elude serologic diagnosis.

Correct interpretation of serologic results is critical to making an accurate diagnosis. Screening serology is sensitive but not specific: a high rate of false positives occurs because surface antigens of *B. canis* cross-react strongly with antibodies to several other nonpathogenic bacterial species. False-positive rates can be as high as 50% to 60% because of cross-reacting antibodies to *Bordetella* spp.,

Pseudomonas spp., *Moraxella* spp., and *B. ovis*. For patients with positive results on a screening serologic test, confirmatory testing (see following paragraphs) is needed because of the high incidence of false positives. For this reason screening tests are recommended at least 1 month before a planned breeding to give time for more accurate confirmatory testing if the initial screening test is positive. False-negative results with screening serologic tests are very rare. A false negative can occur if a recently infected dog or bitch is less than 8 to 12 weeks postinfective exposure and seroconversion has not yet occurred. Otherwise a negative test is usually indicative of a truly negative dog.

Despite improvements in serologic diagnostic methods, confirmatory blood cultures have classically been indicated when the disease is suspected. *B. canis* is readily isolated from the blood of bacteremic individuals for several months after infection. A positive *B. canis* culture establishes a definitive diagnosis and has been advocated as the best diagnostic test in the first 2 months of the disease; however, dogs can become abacteremic after 27 to 64 months.

B. canis is an aerobe; but, unlike other *Brucella* spp., the addition of CO₂ (5% to 10%) may be inhibitory. Multiplication is slow at the optimum temperature of 37°C, and enriched medium (tryptose or trypticase soy media) is needed to support adequate growth. *Brucella* colonies become visible on suitable solid media in 2 to 3 days. A culture can be identified as belonging to the genus *Brucella* on the basis of colony morphology, staining, and slide agglutination with anti-*Brucella* serum. Further classification is best done in a specialized laboratory (Carmichael and Joubert, 1998). In the United States the New York State Diagnostic Laboratory at Cornell University, the Tifton Veterinary Diagnostic and Investigational Laboratory in Georgia, and the University of Florida are recognized as reliable laboratories for definitive testing made necessary by initial positive *B. canis* screening tests in dogs intended for breeding, for clinically affected dogs undergoing evaluation for infertility or abortion, or when outbreaks are under clinical management.

Recently a report of successful PCR identification of *B. canis* in semen from dogs failing to have organisms microbiologically identified suggests that PCR-based assays may be the most sensitive method of testing. Thus PCR testing could be considered as part of the male dog prebreeding evaluation, especially in cases in which management of an outbreak is the concern (Keid et al., 2007).

Brucellosis may be a reportable disease in either the dog or human in certain jurisdictions. Agglutinating antibodies are not protective in the dog.

THERAPY

Infected dogs and bitches should be removed from breeding programs and neutered to minimize transmission potential. Historically antibiotic therapy has not been rewarding, likely because the organism is intracellular and bacteremia periodic. Antibiotic therapy may reduce antibody titers without clearing the infection. Relapses are common. Combination therapy with tetracyclines (doxycycline or minocycline 25 mg/kg BID orally [PO] for

4 weeks) and dihydrostreptomycin (10 to 20 mg/kg BID intramuscularly [IM] or subcutaneously [SC] for 2 weeks, week 1 and 4) or an aminoglycoside (gentamicin 2.5 mg/kg BID IM or SC for 2 weeks, week 1 and 4) has been advocated as most successful; but unavailability, nephrotoxicity, parenteral therapy requirements, and expense remain problematic (Greene and Carmichael, 2006).

Recently one study reported an encouraging outcome of therapy with enrofloxacin (5 mg/kg BID PO for 4 weeks) in a small group of infected dogs and bitches (Wanke, Delpino, and Balth, 2006). Enrofloxacin was not completely efficacious in eliminating *B. canis*, but it maintained fertility and avoided the recurrence of abortions, transmission of the disease to subsequently whelped puppies, and dissemination of microorganisms during parturition.

PREVENTION

Attempts to develop an appropriate vaccination capable of inducing immunity yet not provoking serologic responses that interfere with the diagnosis have not been successful. Presently the development of a vaccination is considered undesirable since the *Brucella* vaccinations evaluated to date have offered only moderate protection and immunized dogs have developed antibodies confounding the serodiagnosis.

Prevention of infection and elimination of infected dogs should be the principal control strategy in kennels. Prevention requires annual testing of all breeding stock and the testing of all dogs to be introduced into a kennel. Ideally two negative screening tests should be obtained at least a month apart before a dog or bitch is introduced into a breeding facility. Confirmed positive dogs should be isolated (euthanasia is advised by many authors),

neutered, treated, and tested monthly (AGID, culture, or PCR) until two consecutive negative tests occur, recognizing that occult infection can still be present.

Private breeders should require screening tests of all bitches presented for breeding and negative results on confirmatory tests if positive results occur during screening before accepting a bitch into their kennel. Stud dogs should be screened appropriately at least annually. Because of the potential for oral transmission, screening of maiden dogs and bitches before breeding is also recommended.

Leptospirosis

KENNETH R. HARKIN, *Manhattan, Kansas*

Canine leptospirosis has been considered a reemerging infection in the United States beginning in the mid-1990s. Similarly, leptospirosis is considered the most globally widespread zoonotic disease, with recent increases in human cases acquired in all settings. Beginning in 2003 and continuing through 2005, an outbreak of canine leptospirosis in Colorado emphasized the need for continued vigilance in recognizing clinical leptospirosis, even in areas where the disease is considered rare. The purpose of this chapter is to present updated information on leptospirosis and discussions of controversial aspects rather than provide a comprehensive overview of the disease.

EPIDEMIOLOGY

Leptospirosis is maintained in domestic and wild-life reservoir hosts in which renal colonization occurs. Leptospiruria results in contamination of surface water, which can include not only lakes, rivers, ponds, and streams but also muddy fields, water bowls, birdbaths, and other stagnant water sources. The prolonged phase of renal colonization and leptospiruria in maintenance hosts, particularly burrowing rodents, is responsible for survival and transmission of the organism in even inhospitable desert environments. Peridomestic wildlife reservoirs, including raccoons, opossums, voles, rats, and other rodents, are the most important in the transmission of disease to dogs in suburban and urban areas, particularly for serovar Grippotyphosa. Endemic infections in cattle and swine herds, along with wildlife, are important in disease transmission to dogs in rural environments.

Based on serologic surveys, Grippotyphosa appears to be the most prevalent infecting serovar of dogs in the United States, although a retrospective study identified Pomona and Bratislava as the most prevalent serovars infecting dogs in northern California, with no significant number of Grippotyphosa infections. Another recent serologic survey (Moore et al., 2006) suggested that serovar Autumnalis was now most prevalent, at least for exposure. However, there are questions as to the relevance of titers to serovar Autumnalis. In a recent study (Barr et al., 2005) dogs that were vaccinated with a leptospirosis vaccine containing serovars Grippotyphosa and Pomona developed elevated titers to serovar Autumnalis without concomitant equivalent increases in titers to serovar Grippotyphosa. The rise in serologically documented cases of Autumnalis correlates with the inclusion of serovars Grippotyphosa and Pomona in the leptospirosis vaccine, and the seropositivity to Autumnalis correlates strongest to serovar Pomona. These findings support the possibility that the increase

in positive titers to serovar Autumnalis is a reflection of vaccination and not a true increase in Autumnalis infection rates.

A number of retrospective studies have consistently shown that the vast majority of cases (~80%) are diagnosed between July and December and most are in dogs in suburban and rural environments. Large-breed dogs are more commonly affected, likely because of the tendency for them to be outside and participating in activities that increase their exposure; and there is a possible breed predisposition in the German shepherd. The potential predisposition for German shepherds has been identified in a number of studies (Ward et al., 2002). A possible explanation for this breed predisposition is suggested by an investigation of human triathletes who contracted leptospirosis in Illinois and Wisconsin. That study documented that humans with the major histocompatibility (MHC) phenotype HLA DQ6 were at greater risk of infection than individuals who did not carry the phenotype. It is also possible that the predisposition for German shepherds is associated with immunoglobulin A deficiency, a relatively common problem in the breed and not a specific MHC phenotype.

DISEASE SYNDROMES

Acute renal failure is the most commonly recognized disease syndrome in dogs, accounting for more than 90% of reported cases. These dogs often present with anorexia, depression, and vomiting and may also demonstrate arthralgia or myalgia, icterus, polyuria and polydipsia, dyspnea from pulmonary hemorrhage or pneumonitis, and oculonasal discharge. Uveitis may be subtle and is present in a large number of dogs with acute renal failure from leptospirosis. Uveitis goes unrecognized in most dogs, particularly when a qualified ophthalmologist is not available for consultation.

Hepatic failure occurs concurrently in 10% to 20% of dogs with acute renal failure but may also be present independently. These dogs typically have moderate-to-marked elevations in serum alanine transaminase (ALT), serum alkaline phosphatase (ALP), and bilirubin, although ALP elevations are typically higher than ALT elevations. Polyuria and polydipsia may occur in the absence of azotemia or any other laboratory abnormalities, and dogs may appear relatively healthy despite their profound polyuria. Urine specific gravity in these dogs is often hyposthenuric, and the urine sediment is usually inactive. The profound polyuria is often misdiagnosed as central diabetes insipidus. Marked fever (often in excess of 40°C) of 2 to 4 days' duration in the absence of clinicopathologic abnormalities often occurs days to weeks

before the onset of nonazotemic polyuria and polydipsia. Less commonly seen syndromes include intestinal intussusceptions, pleural and pericardial effusion, transverse myelitis, and meningitis.

OUTER MEMBRANE PROTEINS

The outer membrane proteins (OMPs) of pathogenic leptospires play a critical role in pathogenicity and development of the host immune response. Antibodies produced to specific proteins are currently under investigation as diagnostic markers, opening up the possibility of commercial diagnostic tests that do not rely on maintenance of stock cultures of leptospires. The expression of certain OMPs is down-regulated in infection, suggesting that they play a role in survival of the organism outside of the host, but would have no usefulness in vaccine development or serodiagnosis. However, the expression of other OMPs is up-regulated during infection, and these OMPs are potential candidates for vaccine development and diagnostic tests.

LipL32, which may be a hemolysin, is the major OMP of pathogenic leptospires and is expressed both *in vitro* and *in vivo*. Its expression is conserved in pathogenic leptospires, and antibodies to LipL32 are consistently identified in sera from infected patients. Although it is immunogenic, LipL32 does not appear to confer protective immunity independently of other OMPs. The transmembrane protein OmpL1 and lipoprotein LipL41 are also conservatively expressed in pathogenic leptospires during infection. Independently they do not confer immunity, but when combined they have a synergistic effect that provides protective immunity. Lig A and Lig B are immunoglobulin-like proteins that can confer protective immunity independently, are up-regulated during infection, and have great promise as vaccine candidates. Their role in pathogenicity is unclear, but leptospires that lose their Lig proteins and *lig* ribonucleic acid transcript expression lose their virulence.

DIAGNOSIS

Leptospirosis should be considered as one of the primary differential diagnoses for any dog that presents with acute renal failure for which the cause is not immediately identified (e.g., ethylene glycol poisoning, pyelonephritis, or aminoglycoside administration). In addition, for any of the previously described disease syndromes of leptospirosis, failure to consider leptospirosis will result in a failure to diagnose.

The microscopic agglutination test (MAT) remains the gold standard for the diagnosis of leptospirosis. Most veterinary diagnostic laboratories in the United States evaluate for antibodies against serovars Canicola, Icterohaemorrhagiae, Grippotyphosa, Pomona, and Hardjo; many also include Bratislava and a few include Autumnalis. Titers of at least 1:800 are supportive of a diagnosis when compatible clinical findings are present, but documentation of a fourfold rising titer over a 2- to 4-week interval is preferred to confirm the diagnosis. When a 2-week convalescent titer is not convincing, a 4-week titer is recommended for confirmation of infection. Identification of

the infecting serovar is not important for therapy but may have epidemiologic significance, especially during outbreaks of disease.

Interpretation of the MAT can be complicated by cross-reactivity, often resulting in equivalently elevated titers to multiple serovars, although the infecting serovar usually provokes the most persistently elevated titer over time. Coinfection with multiple serovars has not been documented. Prior vaccination may also complicate the interpretation of titers obtained by the MAT. Dogs that have been vaccinated recently may have titers as high as 1:3200. Although vaccinal titers often wane within 3 to 4 months, some dogs may have persistently elevated titers. As discussed previously, dogs that have been vaccinated may have elevated titers to nonvaccinal serovars, further complicating the diagnosis. In some cases of leptospirosis dogs may not develop a titer, either because the infecting serovar is not included on the MAT panel or the dog just does not develop an appropriate antibody response. Other diagnostic tests may be necessary in these instances.

The polymerase chain reaction (PCR) assay has promise in the diagnosis of leptospirosis and is available at a number of veterinary diagnostic laboratories. The diagnostic sample of choice is urine (a minimum of 3 to 6 ml is recommended), which can be obtained by free catch, catheterization, or cystocentesis. Other samples (e.g., aqueous humor, fresh kidney or liver, semen, blood, or cerebrospinal fluid) can be evaluated by PCR but are not submitted routinely. There is no appreciable degradation of leptospiral deoxyribonucleic acid (DNA) when the sample is held at room temperature for 72 hours; but, because of the possibility of shipping delays and seasonal high temperatures, the sample should be sent by next-day or 2-day carrier with an ice pack. A positive result indicates that leptospiral DNA was identified in the sample, supporting the diagnosis of leptospirosis. The immune system is efficient at rapidly removing dead leptospires from the kidney; thus, even though it is possible that the PCR is identifying dead leptospires, it is more likely that the sample contains live leptospires. Although the possibility of false-positive results exists from sample contamination, this is an unlikely event in most laboratories. The PCR has the advantage of sensitivity, becoming positive before seroconversion in some dogs, a finding that was confirmed in humans when various tests for the diagnosis of leptospirosis were compared, although most dogs are positive by both serology and PCR when evaluated. Dogs with leptospirosis may have a negative PCR if the number of leptospires in the sample is below the limit of detection of the test, if PCR is performed before establishment of leptospiuria, or if the patient had been treated with appropriate antibiotic therapy before testing. Dogs that are initially PCR positive in the urine will usually still be positive if tested 3 days after initiating intravenous ampicillin therapy. Unlike the MAT, the PCR fails to identify the infecting serovar but is specific for pathogenic leptospires.

Fluorescent-antibody (FA) testing, aimed at identifying the leptospiral organism in urine or tissue, is available at some veterinary diagnostic laboratories. Although the sensitivity of FA testing is better than dark-field

microscopic evaluation of urine or silver staining of tissue, its sensitivity does not match that of PCR. Likewise, nonspecific binding of the antibody may result in false-positive results.

A number of diagnostic tests, including dark-field microscopy (low sensitivity), silver staining of tissues (low sensitivity and specificity), and culture (low sensitivity, requires special media) have very little use to most veterinarians. I recommend the combination of the MAT and PCR for optimizing the diagnosis of leptospirosis.

THERAPY

There are two main components of therapy for leptospirosis: supportive and specific. Supportive therapy for dogs with acute renal failure from leptospirosis traditionally centers on fluid therapy. Polyuric renal failure is more common than oliguric or anuric renal failure, simplifying fluid management. When oliguric or anuric renal failure ensues, management of fluid therapy becomes more complex. Both hemodialysis and peritoneal dialysis have been used successfully in the management of oliguric and anuric renal failure caused by leptospirosis.

The cornerstone of specific therapy is the administration of an appropriate antibiotic. Traditionally ampicillin is used initially in the dog acutely ill with leptospirosis. Recommended ampicillin dosages range from 22 to 40 mg/kg intravenously every 6 to 8 hours, although 25 mg/kg intravenously every 8 hours appears safe and effective. Ampicillin should eliminate the leptospiremic phase but does not eliminate the organism from the renal tubules. The recommendation to continue amoxicillin once oral administration can be tolerated appears rooted in the past treatment standard of penicillin therapy for 2 weeks followed by 2 weeks of dihydrostreptomycin. Dihydrostreptomycin therapy was directed at eliminating the leptospiruric phase but was delayed until full recovery from renal failure was achieved.

Doxycycline eliminates all phases of leptospiral infection and does not carry the nephrotoxic potential seen with other tetracyclines. Although it would be appropriate to administer doxycycline intravenously from the point of initial diagnosis, I still prefer to administer ampicillin initially in acutely ill dogs and then transition to doxycycline at 5 mg/kg orally every 12 hours as soon as oral medications can be tolerated. A treatment course with doxycycline of 3 to 4 weeks is recommended. Dogs with leptospirosis that are not vomiting can be administered doxycycline orally as the first-line of therapy.

Ciprofloxacin has been shown to be effective in the treatment of leptospirosis (improved survival versus the untreated group), and it is suspected that other fluoroquinolones would be equally effective. However, ofloxacin was ineffective in eliminating renal infection in a hamster model of leptospirosis; thus fluoroquinolones may not be an acceptable substitute for doxycycline. The ability of the fluoroquinolones to cross the blood-brain barrier may make them attractive for parenteral use when uveitis or meningitis is present. Although most dogs stop shedding leptospire in the urine soon after beginning doxycycline therapy, I have followed three dogs that remained PCR

positive for leptospire in the urine for prolonged periods (>60 days) and became PCR negative only after the administration of enrofloxacin at 5 mg/kg orally every 12 hours.

In specific situations the use of corticosteroids (dexamethasone, 0.25 mg/kg intravenously [IV] q12h; or prednisone, 2 mg/kg orally [PO] q24h) may be indicated in the management of leptospirosis. Although thrombocytopenia is typically mild (80,000 to 120,000/ μ L), in the rare case that develops severe thrombocytopenia (<20,000/ μ L) with bleeding corticosteroid administration is indicated. Severe thrombocytopenia is a consequence of Kupffer cell phagocytosis and not disseminated intravascular coagulation. In addition, when the serum creatinine continues to climb for more than 10 days despite appropriate fluid therapy and in the presence of polyuria, corticosteroid therapy may help resolve renal parenchymal inflammation and swelling, which may be self-perpetuating despite appropriate leptospirocidal therapy.

PREVENTION

The primary reasons for promoting leptospirosis vaccinations in dogs are minimizing mortality from severe leptospirosis and preventing zoonotic disease. Based on a number of retrospective clinical studies on canine leptospirosis, the overall mortality rate (failure to leave the hospital after acute onset disease) is approximately 20%. A smaller number of dogs develop chronic renal failure, which ultimately results in a shortened life span. Not every dog with environmental exposure to leptospire develops clinical disease (dependent on strain pathogenicity, size of inoculum, previous exposure), but one cannot predict which dogs will fall ill and which ones will die. In my experience German shepherds tend to be at the greatest risk of developing the worst clinical syndromes and have the gravest prognosis. A recent study suggested that serovar Pomona infections were more likely to result in mortality than other serovars.

It is a long-held belief that a humoral immune response and the presence of antibodies at the time of a challenge are responsible for clearing/preventing infection from leptospirosis. This belief has created controversy in recommendations of annual versus semiannual vaccinations since it is well documented that in most animals vaccine titers do not persist for more than 3 to 4 months. However, this paradigm has been challenged. In a recent study (Klaasen et al., 2003) dogs given two vaccines 4 weeks apart were protected from infection with leptospirosis when challenged at 5, 27, or 56 weeks (three different groups of dogs), even though titers were low or not measurable in the vaccinated dogs at 56 weeks. This study demonstrated that anamnestic responses and cell-mediated immunity may be more important than previously considered. This concept has been more conclusively demonstrated in cattle vaccinated with the *Leptospira borgpetersenii* serovar Hardjo bacterin, in which a sustained Th1 or cell-mediated immune response was the critical factor for inducing protective immunity.

Another controversy regarding leptospirosis vaccinations is the concern for vaccine reactions. At one time reactions to leptospirosis vaccines were more common

and were related to production of the bacterin in protein-rich media. Studies in the early 1980s showed that leptospires grown in protein-free medium were equally immunogenic, and this has become the standard for all vaccine manufacturers. There are no studies that show that the leptospirosis component used in vaccines today is responsible for vaccine reactions that are seen in dogs. It is my opinion that antigen load is the critical issue in vaccine reactions, not the leptospirosis component. I suggest that leptospirosis vaccinations be given at a separate time from other vaccinations, if for no other reason than to document which vaccine is responsible for the reaction.

Several authors have cited a report by Feigin et al. (1973) as proof that vaccination for leptospirosis does not prevent the renal carrier state, thus questioning the need for vaccination as part of zoonosis prevention. The report by Feigin et al. (1973) is a fascinating account of human infections in a St. Louis neighborhood, but it does not establish that dogs were responsible for the leptospirosis in the humans. Several studies have documented that vaccinations protect against renal carriage in dogs (Broughton and Scarnell, 1985; Klaasen et al., 2003; Schreiber et al., 2005). Most evidence supports the position that vaccination does dramatically reduce the renal carrier state and has potential value in preventing zoonotic spread.

Bartonellosis

EDWARD B. BREITSCHWERDT, Raleigh, North Carolina

The genus *Bartonella* currently is comprised of at least 20 species and subspecies of vector-transmitted, fastidious, gram-negative bacteria, which are highly adapted to one or more mammalian reservoir hosts (Breitschwerdt and Kordick, 2000; Boulouis et al., 2005). On an evolutionary basis *Bartonella vinsonii* ssp. *berkhoffii* has evolved to cause potentially persistent intravascular infection in dogs and wild canines, including coyotes and foxes. In contrast, *Bartonella henselae* and *Bartonella clarridgeiae* have evolved to cause persistent intravascular infection in domestic cats and wild felid species.

Numerous domestic and wild animals, including bovine, canine, feline, human, and rodent species, can serve as chronically infected reservoir hosts for various *Bartonella* spp. (Breitschwerdt and Kordick, 2000; Boulouis et al., 2005). In addition to the large number of documented reservoir hosts, an increasing number of arthropod vectors, including biting flies, fleas, keds, lice, sandflies, and ticks, have been implicated in the transmission of *Bartonella* spp. (Boulouis et al., 2005; Chomel et al., 2006), although the mode of transmission of any *Bartonella* spp. to domestic or wild canines has not been proven through experimentally controlled vector transmission studies. Epidemiologic evidence and experimental flea transmission studies support an important role for fleas (*Ctenocephalides felis*) in the transmission of *B. henselae* and *B. clarridgeiae* among cats (Boulouis et al., 2005; Chomel et al., 2006). Three other *Bartonella* spp. (*Bartonella koehlariae*, *Bartonella bovis*, and *Bartonella quintana*) have been isolated from cat blood, but the modes of transmission and the reservoir potential of these species in felids have not been definitively established. Epidemiologic evidence supports a role for *Rhipicephalus sanguineus* and perhaps other tick species in the transmission of *B. vinsonii* ssp. *berkhoffii* to dogs. Considering the diversity of *Bartonella* spp., the large number of reservoir hosts and the spectrum of arthropod vectors, and the clinical and diagnostic challenges posed by *Bartonella* spp., transmission in nature may be much more complex than is currently appreciated in human and veterinary medicine.

Once an animal is infected by a bite, scratch, or arthropod, *Bartonella* spp. localize to erythrocytes and endothelial cells, which provide a potentially unique strategy for bacterial persistence within the bloodstream of reservoir or nonreservoir species (Boulouis et al., 2005). In vitro infection of human CD34+ progenitor cells with *B. henselae* suggests that these bacteria are capable of infecting bone marrow progenitor cells, which may contribute to ongoing erythrocytic infection and perhaps bone marrow dysplasia (Mandle et al., 2005). Infection of bone marrow progenitor cells followed by nonhemolytic

intracellular colonization of erythrocytes would preserve *Bartonella* organisms for efficient vector transmission, protect *Bartonella* from the host immune response, facilitate widespread vascular dispersion throughout the tissues of the body, and potentially contribute to decreased antimicrobial efficacy.

In general, persistent bacteremia in a reservoir host does not induce obvious signs of disease or overt pathology. However, immunosuppression (drug or retroviral induced), co-infection with other vector-borne or non-vector-borne pathogens, and preexisting heart valve malformation or injury are factors that facilitate the development of pathology (endocarditis) in animals or humans infected with a reservoir-adapted *Bartonella* spp. Alternatively, when a *Bartonella* spp. is transmitted from a reservoir host (a seemingly well-adapted immunologic association) to a nonreservoir host (a poorly adapted association) by a cat scratch, animal bite, or arthropod vector, infection can result in a seemingly diverse spectrum of clinical and pathologic abnormalities, potentially including polyarthritis, endocarditis, and meningoencephalitis. In humans *Bartonella*-induced disease manifestations can include fever of unknown origin, endocarditis, lymphadenopathy (cat scratch disease [CSD]), granulomatous hepatitis, encephalitis, bacillary angiomatosis, and peliosis hepatis, particularly in immunocompromised individuals (Boulouis et al., 2005; Chomel et al., 2006). Cats are an important zoonotic reservoir host for human infection (CSD), whereas the extent to which dogs and other domestic or wild animals serve as a reservoir for human infection is less well understood.

FELINE BARTONELLOSIS AND CAT SCRATCH DISEASE

The annual number of CSD cases in the United States has been estimated to be between 22,000 and 24,000, with about 2000 cases/year requiring hospitalization (Chomel et al., 2006). Because of large domestic and feral cat populations, thousands of cases may occur annually in Europe and other parts of the world. For nearly a century regional lymphadenopathy has been associated with animal contact, particularly cat scratches. Although historically numerous microorganisms were implicated as the cause of CSD, *B. henselae* is the predominant if not the sole cause of CSD. *B. clarridgeiae*, *B. quintana* and *Afipia felis* are other potential causes of a CSD-like illness in humans (Breitschwerdt and Kordick, 2000; Chomel et al., 2006). In 1992 Regnery and colleagues at the Centers for Disease Control identified seroreactivity to *B. henselae* antigens in 88% of 41 patients with suspected CSD compared to 3% of healthy controls. Subsequently *B. henselae*

deoxyribonucleic acid (DNA) was amplified from lymph node samples of 21 of 25 (84%) patients with suspected CSD using a polymerase chain reaction (PCR) assay. When blood was cultured from cats that had induced CSD in a person, 90% of the cats were found to be bacteremic (Breitschwerdt and Kordick, 2000).

Historically atypical manifestations of CSD in humans have included tonsillitis, encephalitis, cerebral arteritis, arthritis, transverse myelitis, granulomatous hepatitis and/or splenitis, osteolysis, pneumonia, pleural effusion, and thrombocytopenic purpura (Boulouis et al., 2005; Chomel et al., 2006). With the recent identification of *B. henselae* as the causative agent of CSD and the improved availability of culture, serology, and PCR for diagnosis, there are an increasing number of reports of human bartonellosis that historically would have been classified as "atypical CSD." Previously *Bartonella* infection would not have been considered as a differential diagnosis by physicians in patients lacking a history of lymphadenopathy and a cat scratch. Dog bites are a frequent cause of emergency room presentations in the United States and may well represent an underrecognized source of *Bartonella* transmission to humans. Animal bites and scratches can pose a major risk for *Bartonella* transmission to veterinary professionals (Chomel et al., 2006). Avoiding bites, scratches, and contact with saliva and quickly washing any animal-induced wound with copious quantities of water should be emphasized in veterinary practices and elsewhere.

The extent to which members of the genus *Bartonella* are pathogenic for cats remains to be definitively determined. *B. henselae* and *B. clarridgeiae* bacteremia can be documented in 25% to 41% of healthy cats in flea-endemic regions (Chomel et al., 2006). Prevalence of infection varies considerably among cat populations (stray or pets) with an increasing gradient from cold climates (0% in Norway) to warm and humid climates (68% in the Philippines). Cats are usually bacteremic for weeks to months, but some cats have been reported to be bacteremic for more than a year. Young cats (≤ 1 year) are more likely than older cats to be bacteremic, and stray cats are more likely to be bacteremic than pet cats. Self-limiting febrile illness of 48 to 72 hours' duration, mild-to-moderate transient anemia, and transient neurologic dysfunction were observed in cats experimentally infected with *B. henselae* by blood transfusion (Breitschwerdt and Kordick, 2000). Self-limiting fever can occur in naturally infected bacteremic cats following stressors such as surgical procedures. Although unproven, clinical and research findings would suggest that disease manifestations that are transient in nature and resolve spontaneously without antimicrobial treatment can develop in bacteremic cats.

It is obvious that the long-standing evolutionary adaptation between *B. henselae*, flea vectors, and cats as reservoir-adapted hosts supports a minor pathogenic role for these organisms in acute feline illnesses. The extent to which cats with long-standing intravascular infection develop chronic disease manifestations or the extent to which *Bartonella* infection acts as a cofactor in conjunction with other viruses, bacteria, and protozoa is unknown. Because of the high percentage of chronically bacteremic healthy cats in the United States, establishing

a cause-and-effect relationship between disease manifestations and bacteremia in cats has proved challenging. Epidemiologic studies suggest that fever, lymphadenopathy, stomatitis and gingivitis, kidney disease, and lower urinary tract disease are significantly associated with *B. henselae* seroreactivity (Breitschwerdt and Kordick, 2000; Chomel et al., 2006). Rare cases of uveitis and endocarditis have been associated with *B. henselae* infection in cats (Breitschwerdt and Kordick, 2000; Chomel et al., 2006). In experimentally infected cats fever, lymphadenopathy, mild neurologic signs, and reproductive disorders have been reported. Gross necropsy results are unremarkable; however, histopathologic lesions can include peripheral lymph node hyperplasia, splenic follicular hyperplasia, lymphocytic cholangitis/pericholangitis, lymphocytic hepatitis, lymphoplasmacytic myocarditis, and interstitial lymphocytic nephritis. Collectively these findings would indicate that antibiotic treatment should be attempted in seroreactive or bacteremic (culture or PCR+) cats with these or other nonspecific disease manifestations. However, because of the high prevalence of infection in certain cat populations, antibiotics are not routinely recommended for healthy seroreactive or bacteremic cats in flea-endemic areas. There is no evidence that most antibiotics used to treat *Bartonella* infection in cats are curative, and reinfection caused by continued flea infestation would be likely. Therefore rigorous efforts to eliminate and prevent future flea infestations in cats is recommended as a means to decrease the potential of *Bartonella* transmission to humans and to decrease the opportunity for ongoing infection with different *Bartonella* spp. or strain types in cats. Cats experimentally infected with *B. henselae* by blood transfusion do not develop protective immunity following homologous or heterologous challenge; therefore prior infection may not result in protective immunity on subsequent challenge with the same or a different *B. henselae* strain. Cross-species protection does not occur (Boulouis et al., 2005).

CANINE BARTONELLOSIS

Historically *B. vinsonii* ssp. *berkhoffii* has been considered the most frequent *Bartonella* spp. that infects and causes disease in dogs (Boulouis et al., 2005; Chomel et al., 2006). However, this conclusion may not be accurate since culture is an insensitive means of *Bartonella* isolation, sera from dogs have not been systematically screened against a large panel of *Bartonella* spp. antigens, and minimal PCR testing has been performed on tissues from naturally infected dogs. Serologic studies from Hawaii, the United Kingdom, Japan, and the southeastern United States identified *B. henselae* prevalences of 6.5% (2/31 dogs), 3% (3/100 dogs), 7.7% (4/52 dogs), and 27% (82/301 dogs), respectively.

The spectrum of disease induced by *Bartonella* infection in dogs currently is unknown (Boulouis et al., 2005; Chomel et al., 2006). Similar to humans, dogs can be infected with several *Bartonella* spp., including *B. vinsonii* ssp. *berkhoffii*, *B. quintana*, *B. clarridgeiae*, *Bartonella elizabethae*, *Bartonella washoensi*, and *Bartonella bovis*. Endocarditis caused by *B. vinsonii* ssp. *berkhoffii* represents the most thoroughly established disease association

(Breitschwerdt et al., 1999; Chomel et al., 2006). *Bartonella* endocarditis occurs in large-breed dogs with a high predilection for aortic valve involvement. In some dogs intermittent lameness, bone pain, epistaxis, or fever of unknown origin can precede the diagnosis of endocarditis by several months; whereas other dogs present with an acute history of cardiopulmonary decompensation. Cardiac arrhythmias secondary to myocarditis can be detected in dogs without echocardiographic evidence of endocarditis. Infection with *B. henselae* or *B. vinsonii* ssp. *berkhoffii* alone or in conjunction with *Ehrlichia canis* may cause epistaxis in dogs (Breitschwerdt et al., 2005). Based on serologic evidence, *B. vinsonii* ssp. *berkhoffii*, *B. henselae*, or other *Bartonella* spp. appear to contribute to the development of dermatologic lesions indicative of a cutaneous vasculitis, anterior uveitis, polyarthritis, meningoencephalitis, immune-mediated thrombocytopenia (ITP), or immune-mediated hemolytic anemia (IMHA) in dogs (Breitschwerdt et al., 2004; Goodman and Breitschwerdt, 2005; Chomel et al., 2006). Experimentally infection with *B. vinsonii* ssp. *berkhoffii* induces several alterations in immune regulation and immune function (Breitschwerdt and Kordick, 2000). Antinuclear antibodies have been detected in the serum of dogs infected with *B. vinsonii* ssp. *berkhoffii* or *E. canis* or coinfecting with both organisms, which appears to be relatively common, depending on geographic location (Breitschwerdt and Kordick, 2000; Smith, Tompkins, and Breitschwerdt, 2004). Detection of ITP, IMHA, and polyarthritis in a dog in conjunction with finding antinuclear antibodies would be consistent with a diagnosis of systemic lupus erythematosus (SLE). In dogs with a tentative diagnosis of SLE, ruling out infection with a *Bartonella* spp. should be considered.

Although the pathogenicity of all *Bartonella* spp. in dogs remains poorly characterized, it is becoming increasingly clear that species other than *B. vinsonii* ssp. *berkhoffii* can cause disease in dogs. It appears that *B. henselae* can contribute to the development of granulomatous lesions in dogs since organism-specific DNA sequences have been amplified from dogs with peliosis hepatis, granulomatous hepatitis, systemic granulomatous disease with sialoadenitis, and granulomatous lymphadenitis. *B. clarridgeiae* DNA has been amplified and sequenced from the liver of a Doberman pinscher with copper storage disease and from the aortic valve of a dog with vegetative valvular endocarditis. *B. elizabethae*, a species that infects rodents, was PCR amplified and sequenced from an ethylenediaminetetraacetic acid blood sample obtained from a dog that had experienced chronic weight loss culminating in sudden unexplained death. Recently *B. quintana* has been isolated from the blood or heart valves of dogs with endocarditis. These observations indicate that, although presumably infrequent, *Bartonella* spp. that commonly infect cats or rodents and are known to be transmitted by fleas among reservoir hosts may infect dogs and cause serious disease manifestations such as endocarditis or myocarditis. Circumstantial evidence suggests that cats may transmit *Bartonella* spp. to dogs by way of a scratch or bite, as occurs with human CSD.

Following natural infection, *Bartonella* spp. can be found by PCR in the lymph nodes of healthy or sick dogs. *Bartonella*-induced granulomatous lymphadenitis involving the left submandibular lymph node was diag-

nosed in a dog on the basis of seroreactivity to *B. vinsonii* ssp. *berkhoffii* antigens, visualization of Warthin-Starry silver staining bacteria within the lymph node, and PCR amplification followed by southern blot hybridization (Pappalardo et al., 2000). Seven days before enlargement of the lymph node, the owners removed an engorged tick from the dog's left ear. Although *Bartonella* spp. DNA can be amplified by PCR from ticks and although there have been no transmission studies to prove vector competence, this case in conjunction with other epidemiologic evidence suggests that ticks can transmit *Bartonella* spp. to dogs and potentially to humans (Chomel et al., 2006). *B. henselae* DNA has also been amplified and sequenced from the lymph nodes of dogs with generalized granulomatous lymphadenopathy.

DIAGNOSIS OF CANINE AND FELINE BARTONELLOSIS

Seroconversion could be used to confirm acute *Bartonella* infection in a cat or a dog. Seroconversion has been documented in humans with acute cat scratch disease and in cats and dogs following experimental infection. Because acute and convalescent samples are rarely submitted for diagnostic testing, seroconversion has not been reported in a naturally infected cat or dog with an acute illness. The kinetics of the serologic response to *B. henselae* antigens in chronically infected experimental cats is highly variable in degree and duration, and the presence or absence of antibodies does not always correlate with the detection of bacteremia. Although providing useful epidemiologic data, serologic test results from a cat may be of limited clinical use for several reasons. *B. henselae*-specific antibodies are not detectable in some bacteremic cats, and *Bartonella* cannot be cultured from some *B. henselae*-seroreactive cats. Negative blood cultures obtained from *B. henselae*-seroreactive cats may reflect a low level bacteremia or the timing of the blood culture, since experimentally infected cats experience a relapsing pattern of bacteremia (Breitschwerdt and Kordick, 2000). Numerous naturally infected cats are persistently bacteremic, generally in conjunction with low antibody titers. High *B. henselae* antibody titers in cats generally correlate with positive blood cultures. The extent of serologic cross-reactivity to *Bartonella* spp. requires additional clarification since both cats and dogs can be coinfecting with more than one *Bartonella* spp. Although serology can provide very useful diagnostic information, test results must be interpreted in conjunction with other clinical data.

Ideally the diagnosis of *Bartonella* infection should be confirmed by culturing the organism from blood, lymph node, or heart valve or by amplifying organism-specific DNA sequences from tissues using PCR. Unfortunately this diagnostic objective is complicated by a number of factors. Because of a relatively high level of bacteria in cat blood, successful isolation of *B. henselae* or *B. clarridgeiae* from the blood of an infected cat is relatively easy to achieve compared to the difficulty of isolating any *Bartonella* spp. from the blood or tissues of an infected dog. Because of the large number of cats that are chronically infected with *B. henselae* in flea-endemic regions, culture or PCR amplification of *Bartonella* DNA would confirm infection

but would not confirm that *B. henselae* is the cause of clinical or hematologic abnormalities or a specific disease entity in a sick cat. Because conventional isolation techniques have lacked sensitivity, canine bartonellosis is most frequently diagnosed by PCR amplification of organism-specific DNA sequences and/or through serologic testing. In sick dogs detection of *B. henselae*, and more particularly *B. vinsonii* ssp. *berkhoffii*, antibodies should be considered diagnostically relevant to the patient's illness until more data are available to change this assessment. Recently the development of a more sensitive isolation approach using *Bartonella* α -*Proteobacteria* growth medium (BAPGM) followed by PCR has greatly facilitated the molecular detection or isolation of *Bartonella* spp. from the blood of sick or healthy animals and humans. Similar to cats, it appears that dogs can be infected with a *Bartonella* spp. without mounting a diagnostic antibody response. Because very few *Bartonella* organisms are found in sick dog blood samples, combining a more sensitive culture approach with a highly sensitive and specific PCR assay greatly facilitates the detection of active infection in dogs.

TREATMENT OF *BARTONELLA* INFECTIONS

Because of disparate results among human studies and an overall lack of microbiologic data derived from clinical therapeutic trials in animals, numerous issues related to treatment of *Bartonella* infection remain controversial. In contrast to the apparent lack of response to antimicrobial treatment in human CSD patients, bacillary angiomatosis, parenchymal bacillary peliosis, and acute *Bartonella* bacteremia appear to respond to antimicrobial treatment, even in immunocompromised individuals (Boulouis et al., 2005; Chomel et al., 2006). Doxycycline, erythromycin, and rifampin are recommended antibiotics; but clinical improvement has been reported following the use of penicillin, gentamicin, ceftriaxone, ciprofloxacin, and azithromycin. Treatment for 2 weeks in immunocompetent humans and 6 weeks in immunocompromised humans is generally recommended. Relapses associated with bacteremia have been reported in immunocompromised humans despite treatment for 6 weeks. Antimicrobial efficacy has not been established for any antibiotic for eliminating *B. henselae* bacteremia in cats or dogs. Incomplete treatment responses have been reported in experimentally infected cats treated for 2 or 4 weeks with doxycycline or enrofloxacin (Kordick et al., 1997).

HUMAN HEALTH IMPLICATIONS

Based on the annual increase in publications related to *Bartonella* infections in animals and humans during the past decade, it is obvious that members of this genus are gaining increased international scrutiny by physicians and veterinarians. When examining data generated in specific healthy or sick animal populations, it will be important to recognize the exceptional evolutionary adaptation of these microorganisms, which allows them to induce persistent blood-borne infections in both animals and humans. Efficient adaptation to blood and endothelial cells has complicated efforts to detect and define disease causation in association with intravascular

Bartonella infection. As animals function as reservoirs for various *Bartonella* spp., blood-borne infection facilitates a continued transmission cycle via arthropod or animal bites or scratches (Chomel et al., 2006). Animal contact, which in many instances occurs to a wide spectrum of domestic and wild animal species, is an obvious consequence of the daily activities of veterinarians, veterinary technicians, animal health researchers, ranchers, wildlife biologists, and many other individuals in our society. Recently *B. henselae* or *B. vinsonii* ssp. *berkhoffii* infection has been documented in our laboratory in blood samples from humans with extensive arthropod and animal contact. The potential clinical relevance of detecting *Bartonella* spp. in the blood of humans with occupational animal contact remains to be determined. Despite frequent occupational exposure to animals, it is important to acknowledge that most veterinary professionals, ranchers, and wildlife biologists participate in a diversity of outdoor recreational and occupational activities that also increase the opportunity for *Bartonella* transmission by biting arthropods. Therefore the source of infection in these individuals cannot be clearly established.

LEGAL IMPLICATIONS

Except for *Homo sapiens*, veterinarians are responsible for the medical care and general well-being of all of the animal species on this planet. In regard to zoonotic disease transmission, veterinarians play a pivotal role in the public health infrastructure of our nation. Additional prospective studies are necessary to characterize the risk of human *Bartonella* infection following a cat or dog bite and whether these infections are always self-limiting. Despite the long, natural evolutionary history of *Bartonella* and mammals, the legal implications of *Bartonella* transmission from pets to humans in our modern society may create both complications and opportunities for the veterinary profession. Although recent research findings have substantially improved our understanding of the clinical, microbiologic, and zoonotic aspects of diseases caused by *Bartonella* spp., the exact mode of transmission; the relative role of various insect vectors such as biting flies, fleas, lice and ticks; the identification of new reservoir hosts; and the spectrum of animal and human illnesses caused by these organisms remain largely undetermined. The pathogenic potential of these organisms appears to be of considerable importance in dogs and immunocompromised and immunocompetent humans.

CHAPTER 271

Canine and Feline Hemotropic Mycoplasmosis

SÉVERINE TASKER, *Bristol, England, United Kingdom*

Feline and canine hemotropic mycoplasmas (hemoplasmas) are small bacteria that reside on the surface of red blood cells and can mediate hemolytic anemia in their host. Initially the hemoplasmas, including members of the genus *Haemobartonella*, were classified as rickettsial organisms, but gene sequencing analysis and phylogenetic studies have resulted in their reclassification within the genus *Mycoplasma*. *Haemobartonella felis* is now named *Mycoplasma haemofelis*, whereas *Haemobartonella canis* is called *Mycoplasma haemocanis*, and these organisms are collectively known as the hemoplasmas. Molecular studies have also confirmed the existence of additional feline and canine hemoplasmas. These species differ in pathogenicity, and an understanding of their characteristics is important to enable the veterinary clinician to manage cases appropriately.

EXISTENCE OF MULTIPLE SPECIES

M. haemofelis infection is often associated with the development of acute hemolytic anemia in cats. Two additional feline haemoplasma species have now been reported: '*Candidatus M. haemominutum*' and '*Candidatus M. turicensis*.' '*Candidatus M. haemominutum*' is less pathogenic than *M. haemofelis* but can induce

anemia in some circumstances. '*Candidatus M. turicensis*' has only recently been discovered and limited reports suggest that it can induce mild-to-severe anemia. Splenectomy is not necessarily required for these agents to induce disease in their feline hosts, although immunocompromise may play a role in allowing '*Candidatus M. haemominutum*' and '*Candidatus M. turicensis*' to cause disease.

M. haemocanis infection usually results in hemolytic anemia only in splenectomized or immunocompromised dogs. A new canine hemoplasma, '*Candidatus M. haematoparvum*,' has recently been described in association with anemia in a dog that had been splenectomized and was immunosuppressed (Sykes et al., 2004).

Phylogenetic studies have shown that, although *M. haemofelis* and *M. haemocanis* are distinct species, they are closely related. '*Candidatus M. haemominutum*' and '*Candidatus M. haematoparvum*' are also closely related. Some have referred to *M. haemofelis* and *M. haemocanis* as *large* forms of hemoplasma, whereas '*Candidatus M. haemominutum*' and '*Candidatus M. haematoparvum*' are sometimes called *small* forms since the size of the former species, when seen cytologically, may be larger than the latter, although variation does exist. Interestingly, '*Candidatus M. turicensis*' has not been definitively identified

cytologically; thus the morphologic appearance of this species has not been described. In phylogenetic analysis '*Candidatus M. turicensis*' does not group with the previously described feline and canine hemoplasma spp.; instead it groups with rodent hemoplasma species.

PREVALENCE OF INFECTION

Prevalence studies for feline hemoplasma species have now been performed worldwide. '*Candidatus M. haemominutum*' is most common, being identified in 10% to 32.1% of cats sampled in different studies. *M. haemofelis* and '*Candidatus M. turicensis*' infections are less common with rates varying from 1.4% to 6.4% and 1.3% to 26%, respectively. The nature of the cats sampled for these different studies has varied enormously, from healthy cats to cats suspected of having hemoplasmosis, possibly explaining some of the variation in the results obtained. In addition, geographic variation appears to exist, with warmer countries having a higher prevalence of infection. Of additional note is that infection with '*Candidatus M. turicensis*' is often associated with coinfection with either and occasionally both of the two other feline hemoplasma species, particularly '*Candidatus M. haemominutum*.' Further studies are required to determine the prevalence of canine hemoplasmas, but some work suggests that infection with '*Candidatus M. haematoparvum*' is more common than that with *M. haemocanis*, although a recent Swiss study documented the reverse (Wengi et al., 2008). In another study kennel dogs were found to have a higher prevalence of infection with *M. haemocanis* than pet dogs (Kemming et al., 2004).

PATHOGENICITY

Hemoplasma infections induce anemia by causing hemolysis, which is primarily extravascular in nature, although intravascular hemolysis has also been reported. In addition, sequestration of infected red blood cells within the spleen may also result in a reduction in packed cell volume (PCV). An increase in osmotic fragility has been reported in cats infected with *M. haemofelis* and '*Candidatus M. turicensis*.' Differences in pathogenicity exist among hemoplasma species.

'*Candidatus M. haemominutum*'

Experimental '*Candidatus M. haemominutum*' infection of cats does not usually lead to significant clinical signs or anemia, although a fall in erythrocyte parameters can occur. A significant anemia has been seen following '*Candidatus M. haemominutum*' infection in retrovirus-infected (combined feline leukemia virus [FeLV] and feline immunodeficiency virus [FIV] or FeLV alone) cats (George et al., 2002), although a recent study failed to document potentiation of anemia in chronically infected asymptomatic FIV cats (Tasker et al., 2006). Most studies in naturally infected cats have failed to find an association between '*Candidatus M. haemominutum*' infection and anemia. '*Candidatus M. haemominutum*' associated anemia has also been reported in a cat undergoing chemotherapy for lymphoma (De Lorimier and Messick, 2004).

An association between '*Candidatus M. haemominutum*' and renal insufficiency has also been suggested (Willi et al., 2006a), although this causal association may be coincidental in that older cats are more likely to be '*Candidatus M. haemominutum*' infected and have chronic renal insufficiency.

Mycoplasma haemofelis

Experimental infection with *M. haemofelis* often results in a severe hemolytic anemia, although the severity of anemia varies considerably. Some studies of naturally infected cats have found an association between anemia and *M. haemofelis* infection, but others have not. It has been hypothesized that acute infection with *M. haemofelis* can result in severe hemolytic anemia but that chronically infected cats are not anemic (Willi et al., 2006a).

'*Candidatus M. turicensis*'

Experimental studies with '*Candidatus M. turicensis*' are limited in number, but this organism has been shown to induce moderate-to-severe anemia in two cats, being more severe in a cat given methylprednisolone acetate to induce immunosuppression. Difficulties exist in assigning clinical signs solely to '*Candidatus M. turicensis*' infection in naturally infected cats since many '*Candidatus M. turicensis*' infected cats are coinfecting with other feline hemoplasmas. Cats coinfecting with either '*Candidatus M. turicensis*' and '*Candidatus M. haemominutum*' or '*Candidatus M. turicensis*' and *M. haemofelis* have significantly lower PCVs than hemoplasma-free cats, whereas those infected with '*Candidatus M. turicensis*' alone do not (Willi et al., 2006b). In addition, cats naturally infected with '*Candidatus M. turicensis*' often have concurrent diseases. Therefore it is possible that immunosuppression or stress influences the pathogenic potential of this species.

Canine Hemoplasmas

Studies regarding the pathogenicity of canine hemoplasmas are sparse. As mentioned previously, infection usually only results in hemolytic anemia in splenectomized or immunocompromised dogs, and asymptomatic latent *M. haemocanis* infections can be reactivated following splenectomy.

CLINICAL PRESENTATION

The clinical disease that follows hemoplasma infection is influenced by the species of hemoplasma involved, whether there is acute or chronic infection, and whether concurrent disease or immunosuppression is present. Common clinical signs seen in cats and dogs affected by hemoplasma infection include dehydration, anorexia, lethargy, weight loss, depression and intermittent pyrexia, and anemia. Splenomegaly may also be evident.

CLINICAL PATHOLOGY

Pathogenic hemoplasma infection typically causes a regenerative anemia that is macrocytic and hypochromic in nature, although pronounced reticulocytosis is

not always evident. Normoblasts may be present. Positive Coombs' tests, particularly with cold agglutinins, and autoagglutination have been reported in acute hemoplasmosis, indicating the presence of erythrocyte-bound antibodies. Spherocytes may also be evident in canine infections. Icterus is seen occasionally but is uncommon.

The influence of retroviral status on feline hemoplasmosis is not fully understood. Some studies have found that FeLV and/or FIV infection is associated with an increased risk of coinfection with '*Candidatus M. haemominutum*' and *M. haemofelis*. Therefore it seems prudent to perform FeLV and FIV testing in hemoplasma-infected cats, especially if the retroviral status of the cat is not known.

CARRIER STATUS

Long-term carrier status can occur with hemoplasma infection. Our experience at the University of Bristol suggests that this is particularly common with '*Candidatus M. haemominutum*' infection, although suspected clearance of infection has been reported by others with and without antibiotic treatment (Willi et al., 2006a). We have observed that a large proportion of *M. haemofelis*-infected cats spontaneously clear infection from peripheral blood a few months following acute infection; this has also been reported for '*Candidatus M. turicensis*.' However, generalized statements regarding long-term carrier status cannot be made since great variation exists, likely because of differences in the host-organism interaction and hemoplasma isolates. Carrier cats are often asymptomatic, but reactivation of infection can occur and may result in clinical disease (Foley et al., 1998); this is uncommon in our experience.

Little work has been done regarding the time course of carrier status with canine hemoplasmas, but asymptomatic carrier dogs infected with '*Candidatus M. haematoparvum*' and *M. haemocanis* are thought to exist (Kemming et al., 2004; Kenny et al., 2004).

DIAGNOSIS

Examination of Blood Smears

Diagnosis of hemoplasma infection used to rely on cytologic examination of blood smears, but this method has extremely poor sensitivity and variable specificity. Although organisms sometimes may be visible for a short period during peak parasitemia after acute infection, cytology is too insensitive to be relied on for making a diagnosis of hemoplasmosis; thus the polymerase chain reaction (PCR) has emerged as the diagnostic test of choice.

Polymerase Chain Reaction

When designed and executed properly, PCR is extremely sensitive and specific for the diagnosis of hemoplasma infection. It is extremely important that a reputable laboratory carry out the PCR and that the sensitivity and specificity and quality assurance of the PCR assays used be communicated by commercial laboratories so reliability can be evaluated by the practicing veterinarian.

Conventional non-quantitative PCRs can be designed to detect and distinguish all of the feline and canine

hemoplasmas. Real-time quantitative PCRs additionally quantify the amount of hemoplasma deoxyribonucleic acid (DNA) present within blood samples (Tasker et al., 2003). Quantification of the amount of hemoplasma DNA present in a sample may help determine the significance of infection and monitor response to treatment. However, it has been shown that organism numbers in some cats infected with *M. haemofelis* fluctuate markedly and spontaneously, sometimes occurring in regular cycles of increases and decreases in copy number over a long period of time (months), complicating interpretation of quantitative data for this species.

Cats can become PCR-negative during effective antibiotic treatment, but it may take several days or even weeks for the hemoplasma levels to fall below the sensitivity of the PCR (Fig. 271-1). However, it has been found that cats can become PCR positive again after antibiotic treatment is stopped, possibly because of the release of organisms back into the blood from sites of sequestration in the body. Thus a single negative PCR result cannot be taken as evidence of clearance of hemoplasma infection. Obtaining several sequential negative PCR results increases the likelihood that elimination has occurred.

TREATMENT

Antibiotic therapy

Tetracycline derivatives are most commonly used to treat hemoplasma infections, with doxycycline (10mg/kg q24h orally [PO]) the preferred drug. Although controlled studies have been performed only for *M. haemofelis*, based on observations of individual cases doxycycline also has activity against most isolates of the other feline hemoplasmas, as well as the canine hemoplasmas. Esophageal strictures secondary to oral doxycycline treatment have been reported in cats; thus it is recommended that dosing be followed by the administration of water by syringe or food to encourage passage of the drug into the stomach.

Fluoroquinolones can also be effective in treating hemoplasmosis. Enrofloxacin (5mg/kg q24h PO) successfully treated *M. haemofelis* infection in controlled studies. Diffuse retinal degeneration and acute blindness have been reported following enrofloxacin treatment in cats, although this is said to be rare. Marbofloxacin (2 to 5.5mg/kg q24h PO) has also been effective in reducing *M. haemofelis* and '*Candidatus M. haemominutum*' organism numbers in the blood of cats treated in controlled studies using a dosage of 2mg/kg every 24 hours orally, although the fall in '*Candidatus M. haemominutum*' organism numbers was less pronounced than that of *M. haemofelis*.

Unfortunately there is as yet no treatment regimen described that consistently eliminates hemoplasma. Although these treatments effectively treat clinical disease in most cases, they do not always induce consistently negative PCR results (see Fig. 271-1). Work evaluating field cases of hemoplasmosis suggests that different hemoplasma isolates may respond differently to antibiotic treatment regimens. There may be a role for the use of imidocarb dipropionate (5mg/kg intramuscularly [IM] q14days) in refractory hemoplasma cases, but controlled studies evaluating its efficacy are lacking.

Fig. 271-1 Graph illustrating outcome of infection with *M. haemofelis* during periods with and without antibiotic therapy. The left y-axis represents *M. haemofelis* copy number (solid line) that is broadly equivalent to *M. haemofelis* organism number per microliter of blood. The x-axis represents day post-infection with *M. haemofelis* inoculated intravenously on day 0. The right y-axis represents packed cell volume (PCV) (dashed line), the normal reference range being 25% to 45%. The hatched boxes represent those times during which doxycycline antibiotic was administered at a dosage rate of 10 mg/kg q24h orally. The graph shows the increase in *M. haemofelis* copy number over time following initial infection. Doxycycline treatment (initially for only 2 days, and then for a 21-day period) was associated with a corresponding fall in *M. haemofelis* copy number. Although three negative *M. haemofelis* polymerase chain reaction (PCR) results were obtained at the end of, and after, the 21-day doxycycline treatment period (days 49, 53 and 56 after infection), these did not represent clearance of infection since *M. haemofelis* PCR then became positive again, with apparent cycling of *M. haemofelis* copy number over the following 45 days. Therefore a single negative PCR results does not confirm elimination of infection.

Corticosteroid Treatment

The anemia induced by feline hemoplasma infection is in part immune mediated; thus corticosteroids have been recommended as treatment in addition to antibiotics, although studies have not evaluated their effectiveness. The use of corticosteroids (prednisolone, 2 to 4 mg/kg/day PO) may be indicated in cases that are Coombs' positive or in which an inadequate response is seen to antibiotics. However, we have observed clinically ill cats, including ones that are Coombs' positive, respond to antibiotic treatment alone without the need for corticosteroids.

Other Treatment

Supportive care also may be required, notably correction of dehydration with fluid therapy and blood transfusion if the anemia is very severe. Although the mode of transmission of hemoplasma infection in field cases has not been confirmed, transmission by fleas and ticks has been implicated in several studies; thus ectoparasite treatment should also be instigated.

Canine Anaplasma Infection

LEAH A. COHN, *Columbia, Missouri*

STEPHANIE J. KOTTLER, *Columbia, Missouri*

Two species of *Anaplasma* can cause disease in dogs: *Anaplasma platys* and *Anaplasma phagocytophilum*. Infection with *A. platys* leads to infectious cyclic thrombocytopenia. Infection with *A. phagocytophilum* leads to a distinct clinical illness often referred to simply as canine anaplasmosis.

THE ORGANISMS

Each with a worldwide distribution, both *A. platys* and *A. phagocytophilum* are small, obligate intracellular bacteria that replicate in membrane-bound vacuoles of eukaryotic cells. *A. platys* replicates within canine thrombocytes. *A. phagocytophilum* resides in granulocytic white blood cells, primarily neutrophils, but occasionally in eosinophils as well. Known primarily as a pathogen of dogs, inclusions purported to be those of *A. platys* have also been identified in cats. Compared to related organisms, *A. phagocytophilum* is fairly promiscuous in its ability to infect different animal species. The organism may cause disease in a variety of species, including dogs, cats, horses (equine granulocytic "ehrlichiosis"), small ruminants (tick fever), and humans (human granulocytic "ehrlichiosis").

Until recently both *A. platys* and *A. phagocytophilum* were considered species within the genus *Ehrlichia*. Based on classification schemes that use sequence homology of 16S ribosomal ribonucleic acid genes to determine the genetic relation of various organisms and group them taxonomically, some *Ehrlichia*-related organisms were moved from the family Rickettsiaceae into the family Anaplasmataceae. Further, several organisms formerly considered members of the genus *Ehrlichia* were moved to more appropriate genus groups. These included *A. platys* (formerly *Ehrlichia platys*) and several other organisms (*Ehrlichia equi*, *Ehrlichia phagocytophila*, and the human granulocytic ehrlichial agent) that were moved and consolidated into the new species *A. phagocytophilum* (Dumler, 2001). Before sophisticated molecular tools became available, these organisms were grouped taxonomically by morphology, cellular tropism, host species, or other parameters.

DISEASE TRANSMISSION

Ticks are believed to be the primary vectors of transmission for canine *Anaplasma* infection. Although *A. platys* has been isolated from several species of tick, including *Rhipicephalus sanguineus*, vector competence has not been demonstrated for any tick. *Ixodid* ticks are vectors for transmission of *A. phagocytophilum*. The organism is acquired by the tick during feeding and later passed to a

new host through salivary secretions; a minimum feeding time of 24 hours is required for successful transmission of *A. phagocytophilum*. Different species of *Ixodid* ticks serve as vectors in different parts of the world. In Europe *Ixodes ricinus* is the primary vector tick, whereas *Ixodes scapularis* (black-legged or deer tick) is the vector in the upper Midwestern, mid-Atlantic, and northeastern parts of the United States, and *Ixodes pacificus* (western black-legged tick) serves the same role in northern California and the Oregon and Washington coastal regions. Reservoir hosts for *A. phagocytophilum* include white-tailed deer, gray squirrel, white-footed mouse, raccoons, and other rodents. Because of the feeding cycle of *Ixodid* ticks, infection with *A. phagocytophilum* occurs most frequently in the spring to early summer and then again in the fall of the year. Although perinatal transmission of *A. phagocytophilum* has been reported in humans, it is likely at most a minor means of transmission in domestic animals. Infection with either organism also can be acquired iatrogenically via administration of contaminated blood products. Although humans can be infected with *A. phagocytophilum*, there is no evidence of transmission directly from dogs (or cats) to humans.

CLINICAL DISEASE

Infectious Canine Thrombocytopenia

Clinical signs of infection begin within 1 to 2 weeks of experimental inoculation with *A. platys*. Platelet counts drop markedly within a few days and can increase just as rapidly. Thrombocytopenia and recovery occur cyclically at 1- to 2-week intervals. Typically the severity of thrombocytopenia gradually lessens with each subsequent cycle. There seem to be differences in disease severity in different regions of the world. Although clinical signs related to thrombocytopenia (e.g., epistaxis, petechiae) have been reported occasionally, most dogs infected with the strains found in the United States remain well, and infection with *A. platys* is often discovered incidentally. In fact, epidemiologic studies suggest that the prevalence of infection is far greater than might be suspected based on incidence of clinical illness. More pathogenic strains may occur in other parts of the world. Bleeding tendencies, fever, lethargy, weight loss, lymphadenomegaly, and other manifestations of a more severe illness are reported in infected dogs from Greece and Israel. Although strains of *A. platys* outside the United States may be more virulent, it is also possible that coinfection with other pathogens contributes to the more severe clinical disease manifestations in these dogs.

Canine Anaplasmosis, or Granulocytic Anaplasmosis

There is not yet a clear clinical picture of a typical *A. phagocytophilum* infection in dogs. Few experimental infection studies have been carried out in dogs (Egenvall et al., 1998; Lilliehöök, Egenvall, and Tvedten, 1998), and reports of naturally occurring infection may be confounded by lack of a definitive diagnosis or exclusion of coinfection. Until recently infection with *A. phagocytophilum* (then known as *E. equi*) was one of two causes of canine “granulocytic ehrlichiosis.” *Ehrlichia ewingii*, the other cause of granulocytic ehrlichiosis in dogs from the central Midwest and southeastern United States, forms granulocytic morulae that are indistinguishable from those of *A. phagocytophilum*. Dogs infected with *E. ewingii* typically experience an acute illness very similar to that described for dogs infected with *A. phagocytophilum*. Except for crude geography (e.g., a dog from Missouri would be assumed to have *E. ewingii*, whereas a dog from Minnesota would be assumed to have *A. phagocytophilum*), these two infections were seldom differentiated until recently. Therefore retrospective and clinical reports of granulocytic ehrlichiosis might reflect infection with either *A. phagocytophilum* or *E. ewingii*.

To further obfuscate the disease manifestations of *A. phagocytophilum* infection, coinfection with multiple tick-borne pathogens may be common. Both *I. scapularis* and *I. pacificus* serve as transmission vectors for pathogens other than *A. phagocytophilum*, including *Borrelia burgdorferi* (the causative agent of Lyme disease). Based on recent evidence, coinfection with *A. phagocytophilum* and *B. burgdorferi* is common in endemic regions. In addition, sick dogs from such endemic regions were more likely to have coinfections with both *A. phagocytophilum* and *B. burgdorferi* than to have either infection alone. Because clinical signs might be related to coinfection or even to *B. burgdorferi*, descriptions of the clinical syndrome resulting from *A. phagocytophilum* infection must be considered suspect unless the infected dogs are tested for both pathogens.

It is likely that infection can either remain subclinical or result in acute disease manifestations. Clinical signs associated with *A. phagocytophilum* infection are often nonspecific and most commonly include fever, lethargy, and anorexia. Although polyarthritis occurs, it seems to be a more consistent finding during infection with *E. ewingii* than with *A. phagocytophilum*. Most dogs diagnosed with *A. phagocytophilum* infection have musculoskeletal pain, but clearly defined joint pain may or may not be present. Other reported signs include splenomegaly, hepatomegaly, central nervous system signs (e.g., ataxia, seizures), and lymphadenomegaly. Gastrointestinal and respiratory tract signs are rare. To date chronic complications commonly attributed to *E. canis* infection have not been described for *A. phagocytophilum*. With the recent advent of in-clinic diagnostic tests to confirm infection with *A. phagocytophilum* (see following section on Diagnosis), it is likely that a much better-defined understanding of the clinical disease will soon be available.

DIAGNOSIS

Although identification of morulae (elementary or inclusion bodies) on microscopic examination of canine blood

smears can be suggestive of infection with *Anaplasma*, it is at best an insensitive and nonspecific diagnostic tool. On Romanowsky-type (e.g., Giemsa, Diff-Quik) stained peripheral blood smears, morulae of *A. platys* appear as basophilic (blue) inclusion bodies within platelets. It can be difficult to differentiate between *A. platys* inclusion bodies and dense platelet granules via light microscopy. Although inclusions can be found as soon as 1 to 2 weeks after experimental inoculation, it may be extremely difficult to find infected platelets during periods of thrombocytopenia. Morulae can be seen within the cytoplasm of granulocytes from 4 to 18 days after infection with *A. phagocytophilum*. Although most dogs with clinical infection attributed to *A. phagocytophilum* in the recorded veterinary literature were recognized because of observed granulocytic morulae, morulae are not uniformly present during infection. Thus absence of morulae cannot be used to rule out anaplasmosis. Even when granulocytic morulae are visualized, the appearance of *A. phagocytophilum* and *E. ewingii* is identical; thus microscopic visualization of morulae alone cannot confirm infection (Fig. 272-1).

There are no other specific findings on routine blood tests from infected dogs. The most common clinicopathologic abnormality identified during infection with either *A. phagocytophilum* or *A. platys* is thrombocytopenia, which may range in severity from mild to marked. Occasionally dogs with either infection may present with platelet counts within the reference range. Lymphopenia, eosinopenia, neutrophilia, and normocytic normochromic anemia have also been described inconsistently in infected dogs. Rarely *A. phagocytophilum* has been associated with apparent hemolytic anemia and severe thrombocytopenia. Biochemical changes may include hypoalbuminemia and mild-to-moderate increases in alkaline phosphatase activity.

Fig. 272-1 Granulocytic inclusion (i.e., morula) in the neutrophil of a dog. The microscopic appearance of inclusions resulting from infection with *Anaplasma phagocytophilum* are indistinguishable from those resulting from infection with *Ehrlichia ewingii*. (Wright-Giemsa stain, $\times 1000$.) (Image courtesy Dr. Linda Berent, University of Missouri–Veterinary Medical Diagnostic Laboratory.)

A variety of serologic tests have been used to look for antibodies to these pathogenic organisms. There seems to be little serologic cross-reactivity between *E. canis* and *A. phagocytophilum* and essentially no cross-reactivity between *E. canis* and *A. platys*. On the other hand, considerable serologic cross-reactivity is found between the two types of *Anaplasma* infections. Commercial indirect fluorescent antibody tests for one pathogen may provide positive test results when the dog has been exposed to the other pathogen. Because canine granulocytic anaplasmosis is an acute illness, either seroconversion or a four-fold increase in convalescent titers obtained 7 to 21 days after acute titers is required to document active infection (Lester et al., 2005). If chronic *A. platys* infection is detected via positive serology, there may not be a significant rise in titer. Recently a commercial enzyme-linked immunosorbent assay that detects the presence of antibodies to *A. phagocytophilum*, *B. burgdorferi*, *E. canis*, and *Dirofilaria immitis* has been marketed (Snap 4Dx IDEXX Laboratories). Reported sensitivity and specificity of the test for *A. phagocytophilum* is 99.4% and 100%, respectively. Apparently infection with *A. platys* results in a positive test result using this in-clinic diagnostic tool.

Serology documents the dog's antibody response to infection; however, other methods of diagnosis rely on identification of the organism. Visualization of morulae has already been described. Assays based on amplification of nucleic acid sequences (i.e., polymerase chain reaction [PCR]) have been used to identify infected dogs. As with all PCR assays, appropriate primer selection is crucial. Primer sequences can be more or less specific; some detect any of several *Anaplasma* or *Ehrlichia* spp., whereas others are specific for a single species. It is incumbent on the veterinary practitioner to use only a reputable laboratory and to understand what will be detected by the primers used in that laboratory.

THERAPY/PREVENTION

Tetracyclines are the mainstay of treatment for both *A. phagocytophilum* and *A. platys* infection. Doxycycline (5 to 10 mg/kg orally [PO] q12–24h) is recommended. Response to treatment is usually rapid, occurring within 24 to 48 hours. The optimum duration of therapy is unknown, but recommendations range from 10 to 28 days. Persistent infection with *A. phagocytophilum* has been documented experimentally after a short course of therapy, and relapses are noted anecdotally. We recommend a full 28-day course of antibiotic treatment. In most treated dogs serum antibodies revert to low or negative concentrations

within 7 to 8 months after treatment. Lack of rapid clinical response should prompt investigation of other disease processes, including *B. burgdorferi*.

Currently there are no vaccines to prevent either of these infections. In addition, recovered animals seem to be susceptible to reinfection with *A. phagocytophilum*. For now, prevention consists of adequate tick control. Environmental controls can minimize tick exposure but do not completely eliminate the acquisition of new ticks. Chemical methods of tick control usually are warranted. Typical choices include amitraz-impregnated collars, fipronil spray or spot-on formulations, and permethrin spray and spot-on formulations. (Dryden and Payne, 2004) Routine home examinations should be encouraged not only to identify and remove individual ticks but to determine if other aspects of tick prevention are working adequately. The role of routine annual screening for canine *Anaplasma* infection remains to be determined.

American Leishmaniasis

GREGORY C. TROY, Blacksburg, Virginia

North American canine visceral leishmaniasis (CVL) is caused by the protozoan parasite *Leishmania infantum* which is of the MON-1 zymodeme, the primary zymodeme of *Leishmania* endemic to southern Europe (Baneth, 2006; Ferrer, 1992). Autochthonous CVL was first recognized in North America in the early 1980s. Cases of autochthonous CVL are reported in individual dogs from Texas, Maryland, Oklahoma, and North Carolina and in kennels located in Michigan, Alabama, and Virginia (Schantz et al., 2005). Before 2000 most cases in the United States were identified in dogs with travel histories to geographic regions of the world with endemic leishmaniasis (Schantz et al., 2005). Since 2001 this disease has been recognized in 21 states and in two Canadian provinces and is now considered well established in certain canine populations in North America (Gaskin et al., 2002; Schantz et al., 2005).

EPIDEMIOLOGY

CVL is considered a worldwide zoonotic disease. Domestic and wild canids are important reservoir hosts for human visceral leishmaniasis in geographic regions of the world where it is endemic. Ownership of infected dogs in endemic areas is considered a risk factor for human visceral leishmaniasis. In North America risk to humans from infected dogs has not been established because individuals that worked intimately with dogs have not been infected.

The primary mode of transmission of the North American isolate of *Leishmania infantum* is not definitively known at this time (Breitschwerdt and Schantz, 2006; Schantz et al., 2005; Rosypal, Zajac, and Lindsay, 2003). Phlebotomine sandflies of the genus *Lutzomyia* are present in North America, but only *Lutzomyia shannoni* is considered a possible competent insect reservoir (Baneth, 2006; Rosypal, Zajac, and Lindsay, 2003). In kennel situations older dogs and dogs that travel to the southern United States appear more likely to become infected with *L. infantum*, implying that different insect vectors or different modes of transmission play a role in maintenance of infection. Transmission of CVL has occurred by use of whole and packed red cell blood transfusions and by direct and transplacental routes. Experimental infection in mice and dogs with *L. infantum* (strain—*L. infantum* Virginia Tech-1; LIVT-1) has shown low levels of vertical and sexual transmission. These findings provide a plausible explanation for transmission of CVL in kennel situations resulting in low-grade maintenance of infection; these modes of transmission of *L. infantum* may play a

more significant role in North American CVL than in other worldwide geographic regions with CVL.

Leishmania organisms reside intracellularly within macrophages in mammals and as extracellular promastigotes in their insect vector. The promastigote is the infective stage of the parasite, which, when injected into the skin of the dog, is transformed into amastigotes. Amastigote multiplication occurs in macrophages by binary fission within cutaneous, subcutaneous, and visceral tissues.

CLINICAL ASPECTS

The predominant clinical presentation of CVL is a generalized, chronic, debilitating systemic disease process affecting cutaneous and visceral tissues. In humans the disease is divided into three different forms, depending on clinical presentation and the propensity of the infecting species to affect certain tissues. These forms are cutaneous, mucocutaneous, or visceral forms. In dogs cutaneous lesions imply concurrent visceral involvement.

In naturally occurring and experimental canine leishmanial infections, a high percentage of dogs become infected, but a smaller percentage of dogs show overt clinical manifestations of disease. In a recent longitudinal study in dogs conducted over three transmission seasons in Italy, the number of dogs infected with *L. infantum* increased sequentially from 27% to approximately 97% of the dogs by the end of the third transmission season (Oliva et al., 2006). Zero percentage, 16%, and 53% of dogs had compatible clinical signs of leishmaniasis at the end of each year of the 3-year study (Oliva et al., 2006). Most dogs exhibit serologic conversion within 6 to 7 months after exposure. In an experimental study in beagles infected with the LIVT-1 strain and followed for 2 years, seroconversion (indirect immunofluorescent antibody test [IFAT]) occurred at 6 months and persisted for the duration of observation with minor fluctuations in reciprocal serologic titers.

Clinical manifestations described in dogs with CVL in the United States are variable and appear dependent on the phase of disease and state of immunity in the animal, but they are similar to dogs with CVL from other geographic locations. Genetic susceptibility in certain breeds of dogs also plays a role in infection. In an experimental study clinical manifestations were more notable in dogs administered a higher dose of *L. infantum* organisms. Common clinical and historical findings included lethargy, exercise intolerance, weight loss, inappetence, and lameness. Physical abnormalities included weight loss; generalized lymphadenopathy; and periocular, facial, and auricular dermatitis

with exfoliation and development of cutaneous ulcers over bony protuberances, with extension to the trunk and extremities. Onychogryphosis was not observed. Ocular discharge was notable and resulted from keratoconjunctivitis, with no evidence of uveitis or panophthalmitis. Acute polyarthritis was evident in three of four experimentally infected beagles with the LIVT-1 strain and was characterized by purulent exudative synovitis. Administration of nonsteroidal antiinflammatory drugs (NSAIDs) resulted in clinical resolution of lameness within a short time in all dogs. Only one dog required long-term therapy with NSAIDs. Culture of *Leishmania* was attempted from joint effusions but was negative for growth on all occasions.

DIAGNOSIS

A diagnosis of leishmaniasis should be suspected in dogs exhibiting chronic skin lesions, ocular discharge, generalized lymphadenopathy, splenomegaly, and weight loss. Laboratory abnormalities that should heighten clinical suspicion of leishmaniasis include mild nonregenerative anemia, thrombocytopenia, hyperproteinemia, hypergammaglobulinemia, hypoalbuminemia, azotemia, and proteinuria.

A definitive diagnosis of leishmaniasis can be made when amastigotes are observed in tissue samples or by growth of the organism in culture. Splenic, lymph node, and bone marrow aspirates and imprints from skin lesions are commonly used in suspected animals in attempts to identify the organism. Microscopic detection rates of amastigotes range from 20% to 60% and depend on the quality of samples and preparations and time allotted to evaluate samples. In one study of beagles experimentally infected with *Leishmania chagasi* (Rosypal et al., 2005), organisms were identified more frequently in aspirates of bone marrow than lymph node aspirates; two positive control dogs infected for longer than 3 years had cytologically detectable amastigotes for approximately 2 years. However, in another study of beagles infected with the LIVT-1 strain, culture of lymph node aspirates was positive more often than bone marrow culture. The IFAT is considered the standard to which other serologic methods are compared and is useful for evaluating suspected infected dogs (Schantz et al., 2005). A titer of 1:64 is usually considered positive. Titers can fluctuate during the course of the disease, and dogs with titers of 1:64 should be evaluated more comprehensively. Other serologic methods to evaluate suspect dogs include complement fixation, direct agglutination, indirect hemagglutination, antigen specific enzyme-linked immunosorbent assay, Western blot, rK39 (see following paragraph), and an antigen dipstick immunoassay.

A variety of polymerase chain reaction (PCR) strategies (single, nested, real-time) have been used to demonstrate *Leishmania* deoxyribonucleic acid (DNA). PCR using primers that amplify a conserved minicircle region of the kinetoplast (extranuclear DNA structure of parasitic flagellates) that is common to all *Leishmania* spp. is available at several diagnostic laboratories. The sensitivity of PCR testing on blood, bone marrow, and lymph node aspirates is appropriately 90% to 95% and is higher on bone marrow and lymph node samples than on blood (Baneth, 2006; Breitschwerdt and Schantz, 2006). Differences in sensitivities among PCR assays appear to be caused by different

levels of parasitemia present in tissues. PCR test results also support the observation that there are fewer symptomatic dogs than the number of dogs exposed and infected. A recombinant antigen immunoassay (rK39) is a more rapid testing method with fewer technical limitations than IFAT or PCR testing (Scalone et al., 2002). This recombinant antigen is a repetitive immunodominant epitope that mimics a kinesin-related protein that is highly conserved among viscerotropic *Leishmania* spp. This immunoassay has an excellent correlation to the IFAT. In an experimental study the rK39 assay detected 90% of infected dogs (Rosypal et al., 2005). In addition, the rK39 test does not cross-react with antibodies to *Trypanosoma cruzi*, which is a problem with the IFAT test in areas where this parasite may be endemic. The rK39 assay is commercially available (Kalazar Detect Rapid Test, InBios International, Ltd.).

TREATMENT AND PREVENTION

Treatment of infected dogs in the United States is controversial at this time because of lack of effective chemotherapeutics that result in parasitic cures, with the resultant persistently infected dogs potentially increasing the risk of human transmission. Pentavalent antimonials are the primary drugs used in treatment regimens. Meglumine antimoniate (Glucantime, Merial) (100 mg/kg intravenously [IV], subcutaneously [SQ] q24h for 3 to 4 weeks) and sodium stibogluconate (Pentostam, Wellcome Foundation Ltd.) (30 to 50 mg/kg IV, SQ, q24h for 3 to 4 weeks) are parenteral drugs requiring daily administration. Only sodium stibogluconate is available in the United States through the Centers for Disease Control and Prevention. Side effects of these drugs, including vomiting, diarrhea, muscle pain/fibrosis, abscessation, thrombophlebitis, and renal failure, are common and can be severe. Allopurinol (20 mg/kg orally [PO] q12 or 24h), a xanthine oxidase inhibitor, can be used concurrently with the pentavalent antimonials and as a maintenance drug. Dogs treated with meglumine antimoniate and allopurinol had prolonged survival times (>4 years) with fewer relapses (Slappedel and Teske, 1999). Treatment of dogs with these compounds requires frequent monitoring, especially of renal function because of potential nephrotoxicity in dogs that frequently already have renal disease. Additional drugs that show some effectiveness in treatment of leishmaniasis are amphotericin B (desoxycholate, lipid emulsion and liposomal preparations), miltefosine, pentamidine, and aminosidine (Noli and Auxiliz, 2005). Parasitic cures are uncommon with these products, but clinical improvements do result. A recent in vitro study with marbofloxacin could hold promise for a less toxic treatment of leishmaniasis.

Until a definitive mode of transmission is identified in North America, dogs should not be held under crowded conditions, and effective topical insecticides should be used to minimize exposure to possible insect vectors. A commercial vaccine against canine visceral leishmaniasis has been licensed in Brazil and contains the Fucose-Mannose-ligand antigen of *Leishmania donovani* (Nogueira, 2005). This product has proven effective in reducing infection rates in dogs and humans where visceral leishmaniasis is endemic (Leishmune[®], Fort Dodge Saude Animal Ltd.).

CHAPTER 274

Toxoplasmosis

MICHAEL R. LAPPIN, *Fort Collins, Colorado*

Familiarity with *Toxoplasma gondii* is important for all small animal practitioners because of pet ownership issues, as well as the occasional association of *T. gondii* with clinical illness in cats and dogs. The life cycle, diagnosis, treatment, and prevention of feline and canine toxoplasmosis has been reviewed extensively over the years (Dubey and Lappin, 2006). In addition, the American Association of Feline Practitioners and the Centers for Disease Control and Prevention have provided information concerning cat ownership as it relates to *T. gondii* and other infectious agents (Brown et al., 2003; Kaplan, Massur, and Holmes, 2002).^{*} This chapter emphasizes some of the most important points about this disease and provides recently published information concerning the zoonotic and clinical considerations for this protozoan.

AGENT AND EPIDEMIOLOGY

T. gondii is one of the most prevalent parasites infecting warm-blooded vertebrates; a recent survey of clinically ill cats in the United States showed an overall seroprevalence rate of 31.6% (Vollaire, Radecki, and Lappin, 2005). Approximately 20% of dogs in the United States are seropositive for *T. gondii* antibodies. Only cats complete the coccidian life cycle and pass environmentally resistant oocysts in feces. Dogs do not produce *T. gondii* oocysts like cats but can mechanically transmit oocysts after ingesting feline feces. *Sporozoites* develop in oocysts after 1 to 5 days of exposure to oxygen and appropriate environmental temperature and humidity. Thus, to lessen the potential of exposure to *T. gondii* for veterinary staff members in the laboratory, fresh feces should be used for fecal flotation, or the feces should be stored refrigerated until examined. *Tachyzoites* are the rapidly dividing stage of the organism; they disseminate in blood or lymph during active infection and replicate rapidly intracellularly until the cell is destroyed. Tachyzoites can be detected

^{*}www.aafponline.org/resources/guidelines/ZooFinal2003.pdf
www.cdc.gov/ncidod/dpd/parasites/toxoplasmosis/default.htm

in blood, aspirates, and effusions in some dogs or cats with disseminated disease. *Bradyzoites* are the slowly dividing, persistent tissue stage that form in the extraintestinal tissues of infected hosts as immune responses attenuate tachyzoite replication. Bradyzoites form readily in the central nervous system (CNS), muscles, and visceral organs. *T. gondii* bradyzoites can be the source of reactivated acute infection (e.g., during immune suppression by feline immunodeficiency virus [FIV] or high-dose cyclosporine therapy), or they may be associated with some chronic disease manifestations (e.g., uveitis). Infection of warm-blooded vertebrates occurs following ingestion of any of these three life stages of the organism or transplacentally. Cats infected by ingesting *T. gondii* bradyzoites during carnivorous feeding shed oocysts in feces from 3 to 21 days. Fewer numbers of oocysts are shed for longer time periods if sporulated oocysts are ingested. Sporulated oocysts can survive in the environment for months to years and are resistant to most disinfectants. For dogs, cats, and humans it is believed that bradyzoites persist in tissues for the life of the host, regardless of whether drugs with presumed *T. gondii* activity are administered.

CLINICAL FEATURES OF FELINE INFECTION

Approximately 10% to 20% of cats that are experimentally inoculated with *T. gondii* tissue cysts develop self-limiting small bowel diarrhea for 1 to 2 weeks; this is presumed to be caused by local replication of the organism during the intestinal phase of infection. However, detection of *T. gondii* oocysts in feces is rarely reported in studies of client-owned cats with diarrhea, in part because of the short oocyst shedding period. Although *T. gondii* enteroepithelial stages were found in intestinal tissues from two cats with inflammatory bowel disease that responded to anti-*T. gondii* drugs, it is my experience that chronic gastrointestinal disease in cats from toxoplasmosis is uncommon.

Fatal toxoplasmosis can develop during acute dissemination and intracellular replication of tachyzoites; hepatic, pulmonary, CNS, and pancreatic tissues are commonly involved (Dubey and Lappin, 2006). Transplacentally or lactationally infected kittens develop the most severe signs of extraintestinal toxoplasmosis and generally die of pulmonary or hepatic disease. Common clinical findings in cats with disseminated toxoplasmosis include depression, anorexia, fever followed by hypothermia, peritoneal effusion, icterus, and dyspnea. If a host with chronic toxoplasmosis is immunosuppressed, bradyzoites in tissue cysts can replicate rapidly and disseminate again as tachyzoites; this is common in humans with acquired immune deficiency syndrome (AIDS). Disseminated toxoplasmosis has been documented in cats concurrently infected with feline leukemia virus (FeLV), FIV, and feline infectious peritonitis virus. Commonly used clinical doses of glucocorticoids do not appear to predispose to activated toxoplasmosis. However, administration of cyclosporine to cats or dogs with renal transplantations or dermatologic disease has been associated with fatal disseminated toxoplasmosis (Bernstein et al., 1999; Last et al., 2004; Barrs, Martin, and Beatty, 2006).

Chronic toxoplasmosis with vague and recurrent clinical signs of disease appears to occur in some cats. *T. gondii* infection should be on the differential diagnoses list for cats with anterior or posterior uveitis, fever, muscle hyperesthesia, weight loss, anorexia, seizures, ataxia, icterus, diarrhea, or pancreatitis.

Based on results of *T. gondii*-specific aqueous humor antibody and polymerase chain reaction (PCR) studies, toxoplasmosis appears to be one of the most common infectious causes of uveitis in cats. It is unknown why the majority of cats infected with *T. gondii* are subclinically affected and other cats develop clinical signs of disease. Similar to what is reported in humans, kittens infected with *T. gondii* transplacentally or lactationally commonly develop ocular disease. Immune complex formation and deposition in tissues and delayed hypersensitivity reactions may be involved in chronic clinical toxoplasmosis. Since none of the anti-*Toxoplasma* drugs totally clear the body of the organism, recurrence of disease is common. This fact should be made clear to owners in discharge instructions, and the communication noted in the medical record.

CLINICAL FEATURES OF CANINE INFECTION

Before 1988 many dogs diagnosed with toxoplasmosis based on histologic evaluation were truly infected with *Neospora caninum*. However, *T. gondii* infection frequently occurs in dogs and rarely can be associated with clinical disease. The most common syndromes associated with disseminated toxoplasmosis in dogs have involved the respiratory, gastrointestinal, or neuromuscular systems, resulting in fever, vomiting, diarrhea, dyspnea, and icterus. Disseminated toxoplasmosis is most common in immunosuppressed dogs such as those with canine distemper virus infection or those receiving cyclosporine to prevent rejection of a renal transplant.

Neurologic signs depend on the location of the primary lesions and include ataxia, seizures, tremors, cranial nerve deficits, paresis, and paralysis. Dogs with myositis present with weakness, stiff gait, or muscle wasting. Rapid progression to tetraparesis and paralysis with lower motor neuron dysfunction can occur. Myocardial infection resulting in ventricular arrhythmias occurs in some infected dogs. Retinitis, anterior uveitis, iridocyclitis, and optic neuritis occur in some dogs with toxoplasmosis but for unknown reasons seem to be less common than in the cat.

CLINICAL DIAGNOSIS

Cats and dogs with clinical toxoplasmosis can have a variety of clinicopathologic and radiographic abnormalities, but none of the findings alone can be used to document the disease. Nonregenerative anemia, neutrophilic leukocytosis, lymphocytosis, monocytosis, neutropenia, eosinophilia, proteinuria, bilirubinuria, and increases in serum globulins and bilirubin concentration can be seen. In addition, increased activities of creatinine kinase, alanine aminotransferase, alkaline phosphatase, and lipase occur in some affected animals.

Pulmonary toxoplasmosis most commonly causes diffuse interstitial-to-patchy alveolar patterns or pleural effusion. Cerebrospinal fluid (CSF) protein concentrations and cell counts are often higher than normal; the predominant white blood cells in CSF are small mononuclear cells and neutrophils. The detection of these abnormalities should direct the clinician to perform additional, more specific *T. gondii* tests, particularly if there is a high likelihood of exposure to sporulated oocysts or uncooked meat or there is historic or other evidence of immunodeficiency.

The antemortem definitive diagnosis of toxoplasmosis can be made if the organism or its deoxyribonucleic acid (DNA) is demonstrated; this is most likely to be achieved in cats or dogs with acute disseminated disease. Tachyzoites or bradyzoites have been detected in tissues, effusions, bronchoalveolar lavage fluids, aqueous humor, or CSF. Detection of *T. gondii* organisms is unlikely in cats or dogs with chronic disease manifestations. *T. gondii* DNA can be amplified from tissues and fluids; thus PCR detection is considered more sensitive and specific than cytologic or histopathologic detection of the organism. Multiple laboratories offer PCR assays that can amplify DNA of *T. gondii* and *N. caninum* (dogs); these assays should be considered if *T. gondii* or *N. caninum* is suspected but are not documented cytologically. Tissues, fluids, or aspirates for *T. gondii* PCR testing can be maintained frozen until assayed because the DNA is very stable. *T. gondii* PCR assays seem to be less sensitive if performed on formalin-fixed samples; thus use of fresh tissue is preferred. Immunohistochemistry can also be performed on tissues to document the presence of *T. gondii* and to differentiate *T. gondii* from *N. caninum*.

Detection of 10 × 12 micrometer diameter oocysts in feces in cats with diarrhea suggests toxoplasmosis but is not definitive since *Besnoitia* and *Hammondia* infections of cats produce morphologically similar oocysts. In these cases *T. gondii* serology should be performed, and, if the primary infection is *T. gondii*, seroconversion should be documented within 2 to 3 weeks. In dogs *N. caninum* oocysts are morphologically similar to *T. gondii* oocysts. These dogs can be screened for *N. caninum* and *T. gondii* antibodies in 2 to 3 weeks to determine the organism that was associated with the infection.

A multitude of tests for detection of *T. gondii*-specific antibodies (immunoglobulin [Ig]M, IgG, IgA), antigens, and immune complexes have been evaluated (Dubey and Lappin, 2006). Unfortunately test results can be positive in healthy animals, as well as those with clinical signs of toxoplasmosis; thus it is impossible to make an antemortem diagnosis of clinical toxoplasmosis based on results of these tests alone. Of the serum tests, IgM titers correlate best with clinical toxoplasmosis since this antibody class is rarely detected in serum of healthy animals; thus many laboratories offer IgM and IgG test results separately. The antemortem diagnosis of clinical toxoplasmosis can tentatively be based on the combination of (1) clinical signs of disease referable to toxoplasmosis; (2) demonstration of antibodies in serum, which documents exposure to *T. gondii*; (3) demonstration of an IgM titer >1:64 or a fourfold or greater increase in IgG titer, which suggests recent or active infection;

(4) exclusion of other common causes of the clinical syndrome; and (5) positive response to appropriate treatment. In dogs neosporosis and toxoplasmosis appear clinically similar; thus I frequently combine *T. gondii* and *N. caninum* serologic tests in my diagnostic workup of suspect patients.

Some cats and dogs with clinical toxoplasmosis will have reached their maximal IgG titer or will have undergone antibody class shift from IgM to IgG by the time they are serologically evaluated; thus failure to document an increasing IgG titer or a positive IgM titer does not exclude the diagnosis of toxoplasmosis. This problem is most common in cats and dogs with chronic disease manifestations. Some healthy cats and dogs have extremely high serum antibody titers, and some clinically ill cats and dogs have low serum antibody titers, thus the magnitude of titer is relatively unimportant in the clinical diagnosis of toxoplasmosis. Because the organism cannot be cleared from the body, most cats and dogs will be antibody-positive for life; thus there is no clinical use in repeating serum antibody titers after disease manifestations have resolved.

The combination of *T. gondii*-specific antibody detection in aqueous humor or CSF and organism DNA amplification by PCR is the most accurate way to diagnose ocular or CNS toxoplasmosis in cats. *T. gondii*-specific IgA, IgG, and DNA can be detected in aqueous humor and CSF of both normal and clinically ill cats; however, *T. gondii*-specific IgM has only been detected in the aqueous humor or CSF of clinically ill cats and so may be the best indicator of clinical disease (Lappin MR, Unpublished data). My laboratory has rarely amplified *T. gondii* DNA or shown *T. gondii* antibody production in aqueous humor or CSF from dogs. CNS toxoplasmosis and neosporosis can appear clinically similar in dogs; thus I frequently combine PCR testing for both organisms on CSF samples from dogs with inflammatory CNS disease.

T. gondii antigens or DNA can be detected in the blood of healthy cats; the source of the organism is likely bradyzoites from tissue cysts. Since *T. gondii* DNA can be detected in blood of healthy cats, positive PCR results do not always correlate to clinical disease. Whether parasitemia can be documented in more dogs with toxoplasmosis than healthy dogs is currently unknown.

THERAPY

Supportive care should be instituted as needed. I have used clindamycin hydrochloride administered at 10 to 12 mg/kg orally every 12 hours for 4 weeks or trimethoprim-sulfonamide combination administered at 15 mg/kg orally every 12 hours for 4 weeks most frequently for the treatment of clinical feline or canine toxoplasmosis. These two drugs can also be used in combination. Trimethoprim sulfa is likely to penetrate an intact blood-brain barrier better than clindamycin and thus should be considered for CNS toxoplasmosis, particularly if there is a poor response to clindamycin in the first 7 days of therapy. Azithromycin administered at 7.5 mg/kg orally every 12 hours has been used successfully in a limited number of cats and dogs, but the optimal interval or duration of this expensive drug is unknown. Recently a case of azithromycin-resistant,

clindamycin-responsive pulmonic toxoplasmosis in a dog was documented (Lappin MR, unpublished data). It is likely that, just like bacteria, different *T. gondii* isolates have different antimicrobial susceptibilities; thus, if the first drug attempted fails, an alternate drug should be attempted if the organism is still high on the differential list. Pyrimethamine combined with sulfa drugs is effective for the treatment of human toxoplasmosis but commonly results in toxicity in cats; thus I never use the drug for this purpose.

Cats or dogs with systemic clinical signs of toxoplasmosis combined with uveitis should be treated with anti-*Toxoplasma* drugs in combination with topical, oral, or parenteral corticosteroids to avoid secondary glaucoma and lens luxations. Prednisolone acetate (1% solution) applied topically to the eye three to four times daily is generally sufficient. *T. gondii*-seropositive cats or dogs with uveitis that are otherwise normal can be treated with topical glucocorticoids alone unless uveitis is recurrent or persistent. In the latter situation it may be beneficial to administer a drug with anti-*T. gondii* activity.

Clinical signs not involving the eyes or the CNS usually begin to resolve within the first 2 to 3 days of clindamycin or trimethoprim-sulfonamide administration; ocular and CNS toxoplasmosis respond more slowly to therapy. If fever or muscle hyperesthesia is not lessening after 3 days of treatment, other causes should be considered, or an alternate anti-*Toxoplasma* drug prescribed. Recurrence of clinical signs may be more common in cats treated for less than 4 weeks. In cases of pulmonary toxoplasmosis, total resolution of radiographic abnormalities may not occur for several weeks. The prognosis is usually poor for cats or dogs with hepatic or pulmonary disease resulting from organism replication, particularly in those that are immunocompromised.

It is currently unknown whether there is benefit to testing cats or dogs for *T. gondii* infection and treating the seropositive animals before administering cyclosporine therapy for other clinical diseases. If cyclosporine is to be used, it seems prudent to use the lowest dose possible and to attempt to avoid exposure to *T. gondii* by restricting hunting activity and feeding processed foods.

ZOONOTIC ASPECTS AND PREVENTION

T. gondii is an important zoonotic agent. Primary infection of mothers during gestation can lead to clinical toxoplasmosis in the fetus; stillbirth, CNS disease, and ocular disease are common clinical manifestations. Primary infection in immunocompetent individuals results in self-limiting fever, malaise, and lymphadenopathy. As T-helper cells counts decline, approximately 10% of humans with AIDS develop toxoplasmic encephalitis from activation of bradyzoites in tissue cysts. *T. gondii* is known to alter behavior of prey species, which may benefit the organism by allowing the feline definitive host to more easily ingest the parasite and continue the life cycle. Interestingly there have also been a number of papers suggesting that chronic *T. gondii* infection of humans may result in a variety of CNS diseases, including behavior changes and schizophrenia (Flegr, 2007; Webster, 2007). However, to date none of the work has documented a definitive link

to toxoplasmosis; and, because *T. gondii* infection can be acquired in several ways, there is no reason to relinquish a personal cat for this concern.

Humans most commonly acquire toxoplasmosis by ingesting sporulated oocysts or tissue cysts or transplacentally. To prevent toxoplasmosis, humans should avoid eating undercooked meats or ingesting sporulated oocysts. Although owning a pet cat has been associated epidemiologically with acquiring toxoplasmosis in some studies, the majority of work suggests that touching individual cats is probably not a common way to acquire toxoplasmosis for the following reasons: (1) cats generally only shed oocysts for days to several weeks following primary inoculation; (2) repeat oocyst shedding is rare, even in cats receiving glucocorticoids or cyclosporine or in those infected with FIV or FeLV; (3) cats with toxoplasmosis inoculated with tissue cysts 16 months after primary inoculation did not shed oocysts; (4) cats are very fastidious and usually do not allow feces to remain on their skin for time periods long enough to lead to oocyst sporulation (the organism was not isolated from the fur of cats shedding millions of oocysts 7 days previously); (5) increased risk of acquired toxoplasmosis was not associated with cat ownership in studies of veterinary health care providers or humans with AIDS. However, since some cats will repeat oocyst shedding when exposed a second time, feces should always be handled carefully. If a fecal sample from a cat is shown to contain oocysts measuring 10 × 12 microns, it should be assumed that the organism is *T. gondii*. The feces should be collected daily until the oocyst shedding period is complete; administration of clindamycin (25 to 50 mg/kg divided q12h orally [PO]) or sulfonamides (100 mg/kg divided q12h, PO) can reduce levels of oocyst shedding.

Box 274-1

Guidelines for Cat Owners To Avoid Acquiring Toxoplasmosis

- Wash hands after handling cats, especially if you are pregnant or immunocompromised.
- Remove fecal material from the home environment daily.
- If possible, do not have immunocompromised humans clean the litter box. If immunocompromised humans must clean the litter box, they should wear gloves and wash hands thoroughly when finished.
- Use litter box liners and periodically clean the litter box with scalding water and detergent.
- Wear gloves when gardening and wash hands thoroughly when finished.
- Cover children's sandboxes when not in use to lessen fecal contamination by outdoor cats.
- Only feed cats cooked or commercially processed food.
- Control potential transport hosts such as flies and cockroaches that may bring the organism into the home.
- Filter or boil water from sources in the environment.
- Housing cats indoors may lessen their exposure.
- Cook meat for human consumption to 80° C for 15 minutes minimum (medium-well).
- Wear gloves when handling meat and wash hands thoroughly with soap and water when finished.

Since humans are not commonly infected with *T. gondii* from contact with individual cats, testing healthy cats for toxoplasmosis is not recommended (Brown et al., 2003). Fecal examination is an adequate procedure to determine when cats are actively shedding oocysts but cannot predict when a cat has shed oocysts in the past. There is no serologic assay that accurately predicts when a cat shed *T. gondii* oocysts in the past, and most cats that are shedding oocysts are seronegative. Most seropositive cats have completed the oocyst shedding period and are unlikely to repeat shedding; most seronegative cats would shed the organism if infected. If owners are concerned that they may have acquired toxoplasmosis, they should see their doctor for testing. Common sense practices should also be followed (Box 274-1).

CHAPTER 275

Pneumocystosis

REMO LOBETTI, *Bryanston, South Africa*

Pneumocystis carinii is a saprophyte of low virulence that primarily occurs in the mammalian lung. Clinical pneumonia has been reported to occur spontaneously in dogs associated with a suspected immunodeficiency. Airborne transmission is suspected because healthy animals become infected when they are housed with infected animals. It is presumed that the organism may have a dormant life stage in the environment. The taxonomy of *P. carinii* is uncertain. It has been classified as a unicellular protozoan belonging to the phylum Sarcosomastigophora, subphylum Sarcodina. However, its reproductive behavior is similar to that of yeast cells. On the other hand, phylogenetic classification based on 16S-like ribosomal ribonucleic acid sequences indicates that *P. carinii* is most closely related to fungi of the class Ascomycetes, yet it behaves like a protozoan because it is sensitive to drugs used to treat protozoan infections.

The morphology of *P. carinii* and the histopathology of the lesions produced by both human and animal isolates throughout the world are similar. Only a single species name has been assigned to the genus *Pneumocystis*, but antigenic differences suggest that several strains may exist. Although currently controversial, four species have been described: two species that infect dogs and rats, *P. carinii* and *Pneumocystis wakefieldiae*; one species, *Pneumocystis murina*, which infects mice; and *Pneumocystis jirvecii*, which infects humans. Biologic differences among isolates from different hosts are suggested by the relative difficulty of experimental interspecies transmission.

EPIDEMIOLOGY

P. carinii appears to be maintained in nature by transmission from infected to susceptible animals within a species. The primary mode of spread is thought to be airborne

droplet transmission between hosts. The contagious nature of pneumocystosis is suggested by the epidemic spread that has occurred in institutionalized humans. Sporadic case reports may represent an activation of latent infection by stress, crowding, and immunosuppressive therapy during hospitalization of latent carriers. Clinical disease also has been experimentally activated after cortisone therapy, cytotoxic chemotherapy, and irradiation. A higher prevalence of infection has been found in dogs with canine distemper compared with a corresponding control population.

The entire life cycle of *P. carinii* is completed within the alveolar spaces, where organisms adhere in clusters to the pneumocytes. Two main forms, the trophozoite and cyst, are found. Although *Pneumocystis* infections are usually limited to the lung, in humans and in a single dog organisms have been reported in extrapulmonary sites. Severe immunodeficiency states in humans such as acquired immune deficiency syndrome (AIDS) can be associated with lymphatic or hematogenous dissemination of the organisms from the lungs to other tissues. Transmission of infection to an offspring may occur via aspiration of amniotic fluid contaminated by placental infection.

PATHOGENESIS

Pneumocystis can be inhaled from the environment and can colonize the lower respiratory tract of clinically healthy mammals; however, organisms rarely multiply to large numbers in the lungs of clinically healthy hosts. In conditions in which there is impaired host resistance or preexisting pulmonary disease, proliferation of organisms can occur. Alveolocapillary blockage and decreased gaseous exchange result secondary to the overgrowth and clustering of *P. carinii* within the alveolar spaces. Intraalveolar organisms are often accompanied by thickening of alveolar septa, but organisms seldom invade the pulmonary parenchyma and are rarely found in alveolar macrophages. The inflammatory response that the organism provokes contributes to the pulmonary alveolar damage and clinical pathophysiology.

CLINICAL FINDINGS

Most reported canine cases have been in miniature dachshunds younger than 1 year, although cases of pneumocystosis have been reported in a Shetland sheepdog, a Yorkshire terrier, and cavalier King Charles spaniels. The syndrome of common variable immunodeficiency, in which there is absence of B cells resulting in little or no antibody production in association with defective T cells, appears to occur in affected miniature dachshunds and is likely a risk factor for clinical disease in these dogs.

The typical clinical history in dogs with pneumocystosis is that of gradual weight loss and variable polypnea progressing over a period of time. Weight loss, which occurs in spite of a good appetite in most dogs, may be associated with diarrhea and occasional vomiting. Coughing is not always present, but exercise intolerance is present consistently. Infected animals may show some response to antibiotic or cortisone therapy.

Affected dogs generally remain relatively alert and afebrile. Abnormalities on clinical examination include polypnea, tachycardia, and pulmonary crackles on thoracic auscultation. Animals are usually in poor condition, cachectic, and often show dermatologic changes such as superficial bacterial pyoderma and demodicosis. Although the mucous membranes generally are of normal color, in severely affected animals they may be cyanotic.

DIAGNOSIS

Hematologic abnormalities are usually nonspecific, with neutrophilic leukocytosis and left shift seen most consistently; eosinophilia and monocytosis occur less frequently. The white cell response often appears inadequate in light of the pulmonary changes. Polycythemia may occur secondary to arterial hypoxemia from impaired gaseous exchange. Thrombocytosis is often also present. Serum proteins are usually normal with a low-to-low normal globulin level, which correlates with low γ -globulin levels on serum protein electrophoresis. Decreased lymphocyte function and low levels of serum immunoglobulin (Ig)A, IgG, and IgM have been reported. Arterial hypoxemia, hypocapnia, and alkalemia indicate an uncompensated respiratory alkalosis. The P_aO_2 is often lower than would be expected from the clinical signs and thoracic radiographs.

Findings on survey thoracic radiography include diffuse, bilaterally symmetric, alveolar-to-interstitial lung disease. Solitary lesions, unilateral involvement, cavitary lesions, spontaneous pneumothorax, or lobar infiltrate occasionally may be present. Tracheal elevation, right-sided heart enlargement, and pulmonary arterial enlargement reflect cor pulmonale secondary to the chronic pulmonary disease.

The diagnosis of pneumocystosis requires direct demonstration of *P. carinii* in either lung biopsy specimens or respiratory fluids. Transtracheal or endotracheal washings and oropharyngeal secretions may contain organisms, with transtracheal aspirates being very effective in identifying organisms in dogs. Samples for cytology may be obtained by endobronchial brushing and transbronchoscopic biopsy, but these procedures require special endoscopic equipment and involve the risks of general anesthesia. Transtracheal or endotracheal lavage and percutaneous transthoracic needle aspiration are more available to practitioners and have been shown to have a good correlation with transbronchoscopic biopsy findings in confirming a diagnosis. None of the cytologic techniques are as reliable or as definitive as lung biopsy for documenting active pneumocystosis. Unfortunately lung biopsy has the greatest risk of complications such as hemorrhage, secondary infection, pneumothorax, and death from anesthesia. Antimicrobial therapy can begin 24 to 48 hours before specimen collection in a patient suspected of having pneumocystosis without hindering the identification of organisms in the sample. Diff-Quik (a modified Giemsa stain) can be used as a fast and inexpensive screening stain after which negative results can be confirmed with more sensitive staining such as methenamine silver for cysts or with Giemsa for nuclei of intracystic sporozoites and trophozoites.

Other diagnostic tests that have been used include direct or indirect fluorescent antibody test for detecting organisms in tracheal aspirates and immunoperoxidase stains for impression smears and formalin-fixed, paraffin-embedded lung sections. The polymerase chain reaction has been effective in the detection of organisms in bronchoalveolar lavage specimens from humans and lung tissue from dogs. In humans serologic tests have been developed; however, their diagnostic value is uncertain since antigenemia is found in up to 15% of clinically normal humans.

THERAPY

Specific therapy is most beneficial in cases in which the disease has been diagnosed during the early stages. Although a number of drugs have been used in the treatment of *P. carinii*, the two drugs that have been used successfully to treat pneumocystosis are pentamidine isethionate and the combination of trimethoprim and sulfamethoxazole, the latter being the most effective in the dog.

Pentamidine isethionate is an aromatic diamidine used in humans. Its major side effects include impaired renal function, hepatic dysfunction, hypoglycemia, hypotension, hypocalcemia, urticaria, and hematologic disorders. Intramuscular administration of this drug has been successful in treating a dog with pneumocystosis, with the only side effect being localized pain at the injection site. Pentamidine has also been used at a reduced dosage in combination with sulfonamides to lower its toxic side effects. Other aromatic diamidines such as diminazene, imidocarb, and amicarbalide have been more effective than pentamidine in treating experimental *P. carinii* pneumonia.

The combination of trimethoprim and sulfamethoxazole has been found to be more effective and less toxic than pentamidine in treating and preventing *Pneumocystis* pneumonia in immunosuppressed humans. A dosage of 15 mg/kg TID or 30 mg/kg BID for 3 weeks has been used successfully in miniature dachshunds with pneumocystosis. Folic acid supplementation should be given if side effects such as leukopenia and anemia are observed or if long-term therapy is required.

Atovaquone is another drug licensed for the treatment of humans with pneumocystosis. It is not as effective as pentamidine or trimethoprim-sulfamethoxazole but has a reported lower toxicity. Bioavailability is increased when the drug is given with food with a high fat content.

Combination therapy using clindamycin and primaquine has also been effective both in vivo and in vitro, but neither drug is effective alone. Dapsone and trimethoprim or pyrimethamine in combination have been effective in experimental animals and clinical trials in immunosuppressed humans with pneumocystosis. Trimetrexate, a lipid-soluble antifolate, has been given concomitantly with leucovorin to humans with *Pneumocystis* pneumonia and AIDS. As with most of the other drugs, neutropenia with or without thrombocytopenia has been the main

side effect. In experimentally infected animals *P. carinii* is resistant to imidazole antifungal drugs, but the anthelmintics benzimidazole and albendazole have been shown to have some effect.

Supportive care is essential for any patient with pneumocystosis. Oxygen therapy administered by cage, mask, or intubation is needed (Chapter 137); and ventilatory assistance may also be required (Chapter 138). Bronchodilators may help reduce airway resistance. If a patient is receiving immunosuppressive agents, they should be discontinued temporarily; however, antiinflammatory drugs may be indicated. In humans the successful treatment of pneumocystosis results in additional pulmonary dysfunction and a decline in arterial oxygen related to the inflammatory reaction to dying organisms, and the administration of antiinflammatory doses of cortisone has been shown to improve pulmonary function and survival. Nonspecific immunostimulants such as cimetidine and levamisole have been given adjunctively to treat affected miniature dachshunds, but in all probability they have limited effect.

Once a diagnosis of pneumocystosis is made, it is very important that a predisposing immune deficiency state be investigated. In humans prophylactic treatment with trimethoprim-sulfamethoxazole drugs has been used in hospitalized patients who are receiving irradiation or immunosuppressive agents or who have immunodeficiencies and debilitating diseases. Similar precautions are deemed not warranted for pets because pneumocystosis has not been recognized with similar frequency in such instances.

Feline Cytauxzoonosis

J. PAUL WOODS, *Guelph, Ontario, Canada*

Cytauxzoon *felis* is an emerging tick-transmitted intracellular protozoon in wild and domestic cats. In domestic cats this microorganism causes severe disease characterized by hemolytic anemia and circulatory impairment with high mortality. The genus *Cytauxzoon* belongs to the subphylum Apicomplexa, order Piroplasmidae, family Theileriidae, which are parasites of mammals. *Cytauxzoon* exist in two distinct tissue forms: an erythrocyte phase (piroplasm) (Fig. 276-1) and a tissue phase (schizont) (Fig. 276-2). The genus *Cytauxzoon* was designated for species reported initially in African ungulates in which the tissue phase develops in mononuclear phagocytes lining the blood vessels of numerous organs, whereas the genus *Theileria* invades lymphocytes during the schizogenous phase. *Cytauxzoon* are closely related to the genus *Babesia*; however, *Babesia* spp. have an erythrocyte stage exclusively without a tissue phase.

EPIDEMIOLOGY

C. felis was first recognized in 1976 in Missouri. It has now been reported in the south central, southeastern, mid-Atlantic, and Gulf coast states of the United States. The pattern of geographic distribution is probably affected by the availability of both reservoir hosts (wild bobcats) and arthropod vectors (*Dermacentor variabilis*). The natural life cycle of *C. felis* is not completely understood. The cat was presumed to be an accidental terminal host with a predominant rapidly fatal disease, but recent findings of asymptomatic infected cats have led to the possibility of cats serving as an additional reservoir for *C. felis*. In contrast, bobcats (*Lynx rufus*) are the presumed reservoir hosts, acting as persistent carriers of the organism and usually developing only mild or subclinical infection. However, there is a paucity of information on blood parasites of free-ranging cats, and *Cytauxzoon* has only been reported in bobcats since 1982; thus questions remain as to whether this is a new disease of felids or only a newly identified disease. Mountain lions (*Felis concolor*) from Florida and Texas also have been reported to carry the organism. There has been a correlation of disease with tick interchange among wild and domestic felids, with ticks presumably transmitting the organism between cats by feeding. The only tick demonstrated experimentally to be a competent vector for *Cytauxzoon* is *D. variabilis* (American dog tick). Transtadial transmission occurs in ticks, but transovarial transmission has not been demonstrated. However, cytauxzoonosis may be more widespread than previously recognized

because cytauxzoonosis-like diseases have been reported in domestic cats in Zimbabwe and Spain, in Pallas' cats (*Otocolobus manul*) from Mongolia, and in a lion (*Panthera leo*) in Brazil. Experimental studies have revealed no zoonotic or agricultural risk for *C. felis*.

Feline cytauxzoonosis is highly seasonal, occurring in spring to early fall, with the highest incidence in early spring to early summer, which correlates with tick activity. Outdoor cats with access to wooded environments are at greatest risk of infection, presumably because of increased exposure to tick vectors. Within endemic areas there is a large variability in incidence of disease between relatively short distances. In fact, there are hyperendemic foci as suggested by detection of infection in more than one cat in multicat households, a phenomenon likely the result of common exposure to tick populations rather than direct cat-to-cat transmission. Cytauxzoonosis has been most commonly reported in middle-aged cats, but it can occur in cats of any age, with no sex or breed predilections. A recent report suggested young male cats to be at higher risk. A recent study screening for *C. felis* in feral cats in the southeastern United States reported a prevalence of 0.3% with an estimated prevalence range of 0% to 0.8%.

Fig. 276-1 Peripheral blood from a cat with cytauxzoonosis. Four piroplasms are present within erythrocytes. Two of the piroplasms (top) each contain two nuclear areas. Two of the erythrocytes (bottom) contain small particulate stain precipitate that must be differentiated from organisms (Wright-Giemsa stain). (From Meinkoth J, Kocan AA: Feline cytauxzoonosis, *Vet Clin Small Anim* 35:89, 2005, with permission.)

Fig. 276-2 **A**, Impression smear of spleen from a cat with cytauxzoonosis. Five large schizont-containing macrophages are present. Scattered myeloid cells and plasma cells are also present. **B**, Higher magnification of the area shown in **A**. The nucleus of a host cell is outlined by arrowheads. The host cell nucleus contains a greatly enlarged nucleolus. The schizont completely fills the cells' cytoplasm, often being indistinct. In portions of the cells multiple merozoites are seen forming within the schizont, giving the cytoplasm a "packeted" appearance (arrow) (Wright-Giemsa stain). (From Meinkoth J, Kocan AA: Feline cytauxzoonosis, *Vet Clin Small Anim* 35:89, 2005, with permission.)

PATHOGENESIS

The limited information available from investigations of *C. felis* reveals a complex pathogenesis. Experimental studies demonstrate that the clinical disease in domestic cats depends on exposure to the schizogenous tissue phase of *C. felis*. Inoculation with schizont homogenate induces disease, whereas inoculation with only erythrocyte-phase piroplasms results in only erythroparasitemia without schizont development or clinical signs of disease. Cats exposed to infected *D. variabilis* develop both schizogenous phases and erythroparasitemia and become ill with cytauxzoonosis. Piroplasms cannot progress through their natural life cycle without passing through the tick host. Thus the ticks are not just mechanical vectors but are also necessary to complete the *C. felis* life cycle. In ticks, transtadial but not transovarial transmission has been demonstrated. Oral and contact exposure does not result in disease; therefore close contact between cats without tick vectors does not pose a risk for disease transmission.

After infection the organism undergoes schizogony, an asexual reproductive phase, in mononuclear phagocytic cells associated with vessels of almost every organ. As the schizonts (see Fig. 276-2) undergo schizogony and binary fission, macrophages lining the blood vessels enlarge tremendously and occlude venules in liver, spleen, lung, and lymph nodes, resulting in a thrombus-like mechanical obstruction of blood flow and tissue hypoxia. The schizont is associated with clinical disease; the greater the schizont burden, the more severe the clinical illness. Domestic cats have extensive schizont burdens, whereas mildly affected bobcats have a limited and transient schizogenous phase. The tissue phase is also suspected to release toxic, pyrogenic, and vasoactive products that contribute to clinical manifestations. The schizogenous tissue phase, detectable by 12 days after infection, is responsible for the venous congestion, thrombotic disease, and organ failure that lead to death in most cats within 3 weeks of infection.

Schizonts develop merozoites that are released when infected macrophages rupture. Merozoites undergo endocytosis by erythrocytes, giving rise to late-stage erythroparasitemia, recognized as piroplasms (see Fig. 276-1) as the disease progresses. Although graphic, the piroplasm itself is relatively innocuous; however, it may induce erythrocyte destruction and erythrophagocytosis. Cats exposed to just piroplasms remain parasitemic (piroplasms may decrease to a low level) but do not develop protective immunity. In experimental studies of infection a few cats (≈ 4 out of >500 cats) did survive infection from exposure to schizonts. In contrast to the piroplasm-exposed cats, these cats developed protective immunity.

CLINICAL MANIFESTATIONS

Cytauxzoonosis follows an acute course, with the stage of disease determining the presenting clinical signs. In natural infections the prepatent period is between 2 to 3 weeks, with the onset of clinical disease occurring 1 to 3 weeks after infection. The clinical signs are initially nonspecific, consisting of depression, dehydration, and anorexia followed by fever (as high as 40 to 41.6°C [107° F]), icterus, anemia, dark urine, tachycardia, splenomegaly, variable hepatomegaly, reluctance to move, and vocalizing with generalized pain. In late stages the cats are terminally moribund and dyspneic, and after fever peaks the body temperature may subside to normal or frequently become subnormal (24 to 48 hours before death). Miscellaneous neurologic signs observed in some cats have included ataxia, nystagmus, seizures, tetany, aggression, and coma. Typically the course of disease is rapid, and cats usually die within 7 days after the onset of clinical signs. However, some cats survive infection and may remain asymptomatic carriers for months to years.

LABORATORY AND PATHOLOGIC FINDINGS

In cats infected with cytauxzoonosis a complete blood count may reveal any combination of cytopenias. Anemia, probably caused by erythrophagocytosis and characterized as normocytic, normochromic, and nonregenerative, is

common. In contrast to anemia associated with infection from other hemoparasites, the absence of regenerative responses may be because the acute course of the disease gives insufficient time for a regenerative response or because of bone marrow suppression from inflammatory disease. Leukopenia consisting of neutropenia with toxic changes is common. Thrombocytopenia may result from increased consumption. Activated partial thromboplastin time and partial thromboplastin time have been prolonged in some cats.

Red blood cells (RBCs) stained with Wright, Giemsa, or other Romanovsky stains may demonstrate piroplasms (see Fig. 276-1), the erythrocytic phase of *C. felis*. The piroplasms consist of a dark purple, eccentric nucleus within a pale light blue or nearly colorless cytoplasm. There are usually one to two organisms per RBC, but there can be as many as four. The piroplasms are pleomorphic, classically appearing as 1- to 2- μ m-diameter "signet ring" (round to oval with a single peripherally located nucleus). They can also be elongated with a bipolar nucleus ("safety pin"), comma-shaped, linear, or tetrad ("Maltese cross"). The piroplasms are located intracellularly, in contrast to the epicellular location of *Mycoplasma hemofelis*. Piroplasms appear late in the course of disease and may be absent or in very low numbers on initial examination in up to 50% of cases. The proportion of affected RBCs with observable piroplasms is generally low (<1%), and often they are not present at the time of death; however, occasionally infected cats have parasitemia as high as 25%. Piroplasms can be at greatest number at the peripheral and distal edges of blood films.

Biochemical changes found consistently are hyperbilirubinemia and hypoalbuminemia, particularly late in the course of the disease. Other more variable and nonspecific changes can include prerenal azotemia, elevated liver enzymes, hyperglycemia, and electrolyte and acid-base disturbances. Bilirubinuria is common. Diagnostic imaging may reveal splenomegaly, hepatomegaly, effusions, and bronchointerstitial pulmonary pattern. Bone marrow examination may show depletion of mature myeloid cells, toxic change, erythrophagocytosis, and schizont-laden macrophages. Erythrophagocytosis and schizont-laden macrophages are also prominent in smears and histologic sections of spleen (see Fig. 276-2), lymph node, liver, and bone marrow.

Postmortem findings indicate a rapid course of disease with good body condition; pallor; icterus; splenomegaly; lymphadenomegaly; and congested, edematous lungs. There can be petechial and ecchymotic hemorrhages in many tissues, including lungs, urinary bladder, kidneys, heart, and meninges. Abdominal veins may be distended and pleural, pericardial, and peritoneal effusions may be present. Histologic examination reveals characteristic large schizont-laden macrophages within the lumens of small vessels of many organs, including the lungs, spleen, liver, kidneys, lymph nodes, bone marrow, heart, and brain. There is minimal inflammatory reaction in the tissues.

DIAGNOSIS

Initial suspicion of feline cytauxzoonosis is based on compatible clinical signs and laboratory findings of acute-onset fever, depression, icterus, anemia, and

hepatosplenomegaly in a free-roaming cat with exposure to ticks in an endemic area. Definitive diagnosis requires identification of the organism. Blood smear examination may identify piroplasms (see Fig. 276-1); however, disease from the schizogenous phase may precede detectable erythroparasitemia. Also, levels of piroplasms may be low; therefore the laboratory should be alerted to the clinical suspicion for *C. felis* so that specific attention is directed at the RBCs for organisms. Dramatic increases in the number of piroplasms can occur within 24 hours; thus a negative smear should be reevaluated when there is clinical suspicion for *C. felis*. The small pleomorphic piroplasms must be differentiated from *M. hemofelis*, nuclear remnants (Howell-Jolly bodies), artifact (stain precipitates, refractile artifacts, water), and *Babesia felis*. Diagnosis can be difficult and may require a well-made thin blood smear that is thoroughly air dried before staining. Diagnosis should not be based on identification of one presumed organism.

Occasionally macrophages containing schizonts are found on the feathered edge of Wright-stained smears of blood and bone marrow. If parasitemia is not observed, fine-needle aspirates or impression smears of tissues, including lymph nodes, spleen, liver, bone marrow or lung, may identify schizogenous forms of *C. felis*. These organs typically are heavily infiltrated with greatly enlarged schizont-parasitized macrophages (see Fig. 276-2). Similarly postmortem examination reveals characteristic histopathologic findings of *C. felis*. Recently a polymerase chain reaction test to detect subunit ribosomal ribonucleic acid of *C. felis* has become available to confirm the presence of *C. felis*.

THERAPY AND PREVENTION

Feline cytauxzoonosis has a grave prognosis, with virtually 100% mortality occurring soon after illness in experimental and natural infections despite various antimicrobial and supportive therapies. However, there have been recent reports of some cats surviving clinical disease and recovering to an asymptomatic erythroparasitic state (some for >6 years). Unfortunately investigations of the survivor cats have not elucidated if survival was caused by therapeutic management, the survivor cats' innate immunity, detection of previously unrecognized carriers, atypical route of infection (e.g., bite wound) resulting in asymptomatic parasitemia, or a less virulent form of *C. felis*.

Although no definitive antiprotozoal therapy has been proven consistently effective, cats present in severe distress, requiring immediate aggressive supportive therapy. The goal of therapy is to sustain the cat to gain time for its innate defenses to battle the infection and/or for investigational antiprotozoal therapy. Depending on the cat's condition, treatment can involve intravenous fluid therapy to rehydrate and correct metabolic imbalances, prophylactic antibiotics for secondary bacterial infection, heparin (100 to 150 U/kg subcutaneously [SQ] q8h) to minimize thrombus formation and development of disseminated intravascular coagulation, and blood products as needed for anemia.

Administration of definitive antiprotozoal treatments to infected cats is controversial because of drug toxicity, the lack of availability and approval, and mostly the paucity of evidence supporting clinical efficacy. Therapies that have been unsuccessful include parvaquone, buparvaquone, sodium thiacetarsamide, and tetracycline. Therapies that have reported inconsistent success are imidocarb dipropionate (Imizol, Schering Plough Animal Health) at a dosage of 2 to 4 mg/kg every 7 days intramuscularly pretreated with glycopyrrolate (0.005 to 0.01 mg/kg intramuscularly [IM] or SQ); atovaquone (Mepron, GlaxoSmithKline) at a dosage of 15 mg/kg every 8 hours orally for 10 days combined with azithromycin (Zithromax, Pfizer) at a dosage of 10 mg/kg every 24 hours orally for 10 days. Although unavailable in North America, another therapy is diminazene aceturate (Berenil, Intervet) at a dosage of 2 mg/kg every 7 days intramuscularly. Although at present a vaccine is not available, one of the surviving experimental cats was resistant to subsequent challenge with lethal doses of *C. felis*, suggesting that it may be possible to vaccinate cats against *C. felis*.

Until better therapy is developed, prevention of infection is paramount. Transmission cannot occur directly from cat to cat; therefore prevention involves minimizing chances of infection from the tick vector by indoor confinement during tick season, avoidance of rural wooded areas, and ectoparasite control (e.g., pyrethrins, fipronil). It is unknown how long a tick must be attached to transmit the disease. Feline blood donors should be screened and free of ectoparasites (ideally kept indoors). Transfusions from recovered cats do not result in illness even if piroplasm-containing erythrocytes are transfused; however, recently infected cats can transmit

schizont-containing circulating monocytes, which can cause disease.

Despite its geographic restrictions, feline cytauxzoonosis is more widespread than previously reported. Recently cases have been recognized in new regions and with increased frequency in previous endemic areas. This change could be the result of changes in distribution, prevalence, or transmission of infected ticks or infected reservoir animals. Concomitantly there has been an increase in recognition and diagnosis by veterinarians. Because of the potential dangers of spread by importation, veterinarians outside endemic areas need to be cognizant of feline cytauxzoonosis and aware of the potential concern for domestic and exotic cats in areas with appropriate reservoirs and tick vectors.

Systemic Fungal Infections

RANCE K. SELLON, *Pullman, Washington*
ALFRED M. LEGENDRE, *Knoxville, Tennessee*

The systemic fungal infections are a collection of well-known and well-described conditions causing clinical signs of multisystemic disease. Most discussions of systemic fungal infections focus on four organisms: *Blastomyces dermatitidis*, *Coccidioides immitis*, *Histoplasma capsulatum*, and *Cryptococcus neoformans*. Most of the information about the pathology and pathophysiology of these infections has been well described in other texts and will not be repeated. This chapter summarizes important findings about the epidemiology of infection, spectrum of clinical disease, and diagnostic developments published in the recent veterinary medical literature. Finally, therapeutic approaches are described for the common systemic mycotic infections.

EPIDEMIOLOGY

In the United States the principal endemic areas of infection for each of the systemic fungal organisms remain constant (Table 277-1). However, some systemic fungal infections have occurred in patients living in areas outside the typical foci of endemic fungal infection. In one report two cats that had not traveled outside of California had confirmed histoplasmosis. The cats lived in an area where there had been recent soil disruption. Interestingly, both of the cats in this report were noted to be completely indoor cats. An outbreak of cryptococcosis on Vancouver Island, BC, Canada saw a spike in disease of both humans and animals (Kidd et al., 2004). In contrast to infection with *C. neoformans*, affected patients were infected with *Cryptococcus gattii*, a species of *Cryptococcus* more prevalent in Australia. Blastomycosis has been documented recently in humans living in Colorado who were working with prairie dogs, potentially extending the distribution of this organism westward.

Although animals that go outdoors are at the greatest risk of exposure to infection, animals that are exclusively indoors have also contracted systemic fungal infections. In addition to the cats with acquired histoplasmosis, blastomycosis has been documented in strictly indoor cats. In humans acquisition of systemic fungal infection (histoplasmosis) has been linked to air-handling systems that channel infectious organisms into buildings (Luby et al., 2005) and a similar means may operate to cause infection in indoor animals. As with the California cats, disruption of soil or ground surface has been associated with infection in humans in nearby buildings.

The clinician's assessment of risk of infection/exposure should consider the possibility of infection in nontraditional

areas. Understanding the widening geographic distributions that have emerged in humans could also serve as a sentinel warning for veterinarians in such areas.

Additional studies have explored the risk factors for canine infection with *C. immitis*. Dogs that spent a lot of time outdoors, that roamed over a large surface area, and that spent time walking across the desert had a greater risk of *C. immitis* infection than mainly indoor dogs or dogs that walked on sidewalks. (Butkiewicz et al., 2005). Many dogs in an endemic area become infected with *C. immitis* (as determined by development of *C. immitis* antibodies), but few actually develop clinical disease.

CLINICAL DISEASE

The spectrum of clinical disease caused by the systemic fungal organisms is well known to clinicians that practice in endemic areas; each of the organisms has a predilection for certain organ systems, and the disease typically reflects affected organs. Common to most of the systemic fungal organisms are respiratory disease, bone infection, central nervous system infection (including eyes), lymph node involvement, and skin lesions (Table 277-2). An additional presentation for coccidioidomycosis is pericardial effusion. In 17 dogs with *C. immitis*-induced pericardial disease, affected dogs had clinical signs typical of pericardial disease and right heart failure: abdominal effusion, muffled heart sounds, poor pulse quality, tachypnea, and jugular pulses (Heinritz, et al., 2005). Cardiac ultrasound examinations documented the presence of pericardial effusion and thickened pericardium in most of the dogs. Subtotal pericardectomy was associated with resolution of clinical signs of right heart failure but was also associated with high (23.5%) perioperative mortality; however, the exact cause of death was established in few of the dogs. There was pyogranulomatous pericarditis in all dogs, and there were *C. immitis* spherules in a majority of dogs. In addition to surgical treatment, dogs with pericardial coccidioidomycosis were also treated with antifungal drugs.

Cardiovascular disease is uncommon in dogs with blastomycosis, but there was a report of eight dogs with cardiovascular blastomycosis (Schmiedt, et al., 2006). Affected dogs had clinical signs typical of blastomycosis, including fever and signs of respiratory disease that reflected fungal pneumonia (lethargy, cough, dyspnea). Some dogs had syncope and cardiac arrhythmias, including atrioventricular blocks. Most had echocardiographic abnormalities that varied from mass-like lesions to evidence of pulmonary hypertension and associated right-sided cardiomegaly.

Table 277-1

Usual Geographic Distribution of the Systemic Fungal Infections

Organism	Geographic Distribution
<i>Coccidioides immitis</i>	Southwestern United States, especially California and Arizona; Mexico; Central America; South America
<i>Histoplasma capsulatum</i>	United States primarily east of the Mississippi river; Central America; South America
<i>Blastomyces dermatitidis</i>	Ohio, Missouri and Mississippi river drainages; mid-Atlantic states (Georgia, South Carolina, North Carolina, Virginia, Maryland); Canada (Ontario, Manitoba, Quebec)
<i>Cryptococcus neoformans</i>	Worldwide
<i>Cryptococcus gattii</i>	Tropical and subtropical regions worldwide; Vancouver Island and Vancouver, British Columbia, Canada

Necropsy lesions included myocardial blastomycosis, blastomycosis-induced epicarditis or pericarditis, infection of the adventitia of the aorta, and inflammation and fibrosis of the atrioventricular nodal region. Typical blastomycosis lesions were found in other organs. Although the authors speculated that cardiac involvement in dogs with blastomycosis is likely more widespread than recognized in this retrospective study, it still appears to be uncommon. Nevertheless, blastomycosis should be suspected in dogs with clinical signs of myocardial or conduction system disease.

Blastomycosis is an uncommon disease in cats compared to dogs, but the spectrum of clinical disease in eight cats with blastomycosis resembled the disease in dogs (Gilor, et al., 2006). Fever, lethargy, anorexia, and

Table 277-2

Systems Commonly Affected in Patients With Systemic Fungal Infections*

Organism	Organ Systems
<i>Coccidioides immitis</i>	Respiratory tract, skeleton, skin, pericardium
<i>Histoplasma capsulatum</i>	Respiratory tract, liver, spleen, gastrointestinal tract (dog), skeleton, eyes
<i>Blastomyces dermatitidis</i>	Respiratory tract, bone, lymph nodes, eyes, brain, skin/ subcutaneous tissue, external nares
<i>Cryptococcus neoformans</i> ; <i>C. gattii</i>	Nasal cavity, skin, eyes, central nervous system, lymph nodes

*In any given patient, dissemination to other organs is possible.

weight loss were common clinical complaints. Cats with blastomycosis had skin and respiratory tract disease (dyspnea, tachypnea, cough). Skin lesions were primarily nonulcerated dermal masses; in contrast to cutaneous blastomycosis in dogs, in which draining lesions are common, the cutaneous lesions in these cats were not draining. Peripheral lymph node enlargement was not seen in any of the cats. Chorioretinitis and central nervous system disease were also observed. Results of complete blood count and serum biochemical profile were nonspecific in the cats of the study. Thoracic radiographs of affected cats demonstrated nodular interstitial-to-alveolar patterns and consolidation. Involvement of the right cranial lung lobe was common, and diffuse bronchial patterns were also frequently observed. As is true with dogs, antemortem diagnosis of blastomycosis in the cats of this study was accomplished by cytologic identification of organisms obtained from aspirates/imprints (skin, lungs, spleen) or lavage of the respiratory tract.

DIAGNOSIS

The definitive diagnosis of all of the systemic fungal infections is established by demonstration of organisms in samples obtained for cytologic or histopathologic examination. With the exception of cryptococcosis, for which serologic assays detect capsular antigen, diagnosis of the other fungal infections based on serologic assays has remained problematic, typically because of low sensitivity and/or specificity of assays that detect antibody. Radioimmunoassays that detect antibody to the WI-1 antigen, the major surface protein of *B. dermatitidis*, have proven more sensitive and specific than assays that detect antibody to *B. dermatitidis* antigen A. However, the radioimmunoassay is not yet available commercially.

Other developments in the diagnosis of the systemic fungal infections by serologic assays in humans have seen initial translation to veterinary medicine. Diagnosis of canine blastomycosis by detection of specific antigen in serum or urine is promising (Spector et al., 2006). The urine antigen assay is more sensitive than the serum assay. The sensitivity and specificity of the urine assay was 93% and 98%, respectively, when evaluating known positive and negative samples. The assay may also have application in determining duration of treatment, but further studies are needed. Additional information on this assay can be found at www.miravistalabs.com. There is cross-reactivity between the *Histoplasma* and *Blastomyces* organisms. There is also an antigen assay for histoplasmosis, but no studies have been published yet on its application in dogs and cats. These antigen assays are currently available.

The work by Shubitz and associates (2005) indicated that, because of overlap in titers between subclinically and clinically infected dogs, serologic titers alone are insufficient to establish a definitive diagnosis of coccidioidomycosis. Thus the diagnosis of this infection requires that additional supportive information (physical examination abnormalities, laboratory abnormalities, radiographic imaging, cytology, and histology) be obtained to establish a clinical diagnosis.

Table 277-3

Therapeutic Suggestions for the Systemic Fungal Infections*

Organism	Treatment Recommendations†‡
<i>Coccidioides immitis</i>	Ketoconazole [§] 10 mg/kg PO q12h or fluconazole 10 mg/kg PO q12h
<i>Histoplasma capsulatum</i>	Itraconazole [§] 5-10 mg/kg PO q12-24h Amphotericin B 0.5 mg/kg IV q48h for gastrointestinal infection
<i>Blastomyces dermatitidis</i>	Dogs: itraconazole 5 mg/kg PO q24h Cats: itraconazole 10 mg/kg PO daily
<i>Cryptococcus neoformans</i> ; <i>C. gattii</i>	Cat: itraconazole 50-100mg/cat daily; terbinafine 10 mg/kg/day for cats that develop resistance to azoles Dog: optimal therapy not established, but itraconazole 10 mg/kg/day or amphotericin B 1 mg/kg intravenously three times weekly is suggested

*Initial suggestions only; for more comprehensive treatment information, consult Bonagura JD, editor: *Kirk's current veterinary therapy XIII (small animal practice)*, ed XIII, Philadelphia, 2000; or relevant chapters in Greene CE, editor: *Infectious diseases of the dog and cat*, ed 3, Philadelphia, 2006, Saunders Elsevier.

†If unfamiliar with drugs or their administration, please consult a veterinary formulary or other suggested readings.

‡Duration of therapy for most is a minimum of 60 to 90 days, or at least 30 days beyond resolution of all clinical signs. *C. immitis* infections may require longer treatment periods.

§Give with food to increase absorption.

TREATMENT

A number of newer antifungal drugs have been developed and proven efficacious in the treatment of the systemic fungal infections in humans. Many belong to the azole class of drugs that includes itraconazole and ketoconazole. Some of the newer azoles used in humans include voriconazole, posaconazole, and ravuconazole. Although such drugs have proven to be of benefit in humans with fungal infections refractory to therapy with the older azoles such as itraconazole, ketoconazole, and fluconazole, there are no published investigations in small animal patients. A common feature of these drugs is the high cost for these agents. Currently accepted recommendations for the treatment of the various systemic fungal infections are summarized in Table 277-3.

Pythiosis and Lagenidiosis

AMY M. GROOTERS, *Baton Rouge, Louisiana*

Pythium insidiosum and *Lagenidium* spp., the causative agents of pythiosis and lagenidiosis, are pathogenic “water molds” in the class Oomycetes. Although they are often grouped with fungi because they grow on mycologic media and produce hyphal structures in tissue, they differ from true fungi in producing motile, flagellate zoospores; having cell walls that lack chitin; and having cell membranes that generally lack ergosterol. Both pythiosis and lagenidiosis cause lesions characterized by eosinophilic and pyogranulomatous inflammation associated with broad, irregularly branching, sparsely septate hyphae; and as a result they are often confused with zygomycosis (infections caused by true fungi in the class Zygomycetes, which produce similar lesions). Although the clinical syndromes associated with *P. insidiosum* infection have been described for many decades, *Lagenidium* spp. have only been recognized as mammalian pathogens since 1999.

PYTHIOSIS

P. insidiosum infection is a devastating and often fatal cause of gastrointestinal or cutaneous lesions in dogs and cats. In small animal patients, pythiosis is encountered most often in the southeastern United States but has also been identified in animals living in New Jersey, Virginia, Kentucky, southern Illinois, Indiana, Oklahoma, Missouri, Kansas, Arizona, California, and the Cayman Islands. Young large-breed dogs (especially outdoor working breeds such as Labrador retrievers) are most often infected. In cats specific breed and sex predilections have not been observed in the few cases that have been reported to date. However, the development of cutaneous pythiosis in very young animals appears to occur more often in cats than in dogs. Of 27 cats with cutaneous pythiosis diagnosed through my laboratory in the past 8 years, 11 were less than 1 year old, with an age range of 4 months to 9 years.

The infective form of *P. insidiosum* is thought to be the motile biflagellate zoospore, which is released into aquatic environments and likely causes infection by encysting in damaged skin or gastrointestinal mucosa. Many dogs with pythiosis have a history of recurrent exposure to warm freshwater habitats. However, disease is also identified regularly in suburban house dogs with no history of access to lakes or ponds. Affected animals typically are immunocompetent and otherwise healthy.

Clinical Findings

Gastrointestinal Pythiosis

In dogs gastrointestinal pythiosis typically results in severe, segmental transmural thickening of the stomach, small intestine, colon, rectum, or rarely the esophagus. The gastric

outflow area, proximal duodenum, and ileocolic junction are the most frequently affected locations; and it is not unusual to find two or more segmental lesions in the same patient. Mesenteric lymphadenopathy is common but most often represents reactive hyperplasia rather than infection. Involvement of the mesenteric root may cause severe enlargement of mesenteric lymph nodes, which are typically embedded in a single large, firm granulomatous mass that is palpable in the midabdomen. Extension of disease into mesenteric vessels may result in bowel ischemia, infarction, perforation, or acute hemoabdomen. In addition, infection in gastrointestinal tissues may extend into contiguous organs such as pancreas and uterus. Gastrointestinal pythiosis is rare in cats but was recently described in two young adult male cats with focal intestinal lesions that were amenable to surgical resection (Rakich, Grooters, and Tang, 2005).

Clinical signs associated with gastrointestinal pythiosis include weight loss, vomiting, diarrhea, and hematochezia. Physical examination often reveals a very thin body condition and a palpable abdominal mass. Signs of systemic illness such as lethargy or depression typically are not present unless intestinal obstruction, infarction, or perforation occurs. Laboratory abnormalities that may be associated with pythiosis include eosinophilia, anemia, hyperglobulinemia, hypoalbuminemia, and rarely hypercalcemia. Abdominal radiography and sonography usually reveal severe segmental thickening of the gastrointestinal tract, an abdominal mass, and/or mesenteric lymphadenopathy.

Cutaneous Pythiosis

Cutaneous pythiosis in dogs typically causes nonhealing wounds and invasive masses that contain ulcerated nodules and draining tracts, most often involving the extremities, tail head, ventral neck, or perineum. In contrast to gastrointestinal pythiosis, regional lymphadenopathy in dogs with cutaneous pythiosis usually reflects extension or postsurgical recurrence of infection rather than just reactive inflammation. Cutaneous and gastrointestinal lesions are rarely encountered together in the same patient.

Cats with pythiosis most often present with nasopharyngeal lesions; invasive subcutaneous masses in the periorbital, tail head, or inguinal regions; or draining nodular lesions or ulcerated plaquelike lesions on the extremities, sometimes centered on the digits or footpad. In contrast to dogs, cats with pythiosis often have firm, nodular, subcutaneous lesions without overlying cutaneous lesions or alopecia.

Diagnosis

Cytology and Histopathology

In dogs with pythiosis pyogranulomatous and eosinophilic inflammation is often apparent on cytologic evaluation of

exudate from draining tracts, impression smears made from ulcerated skin lesions, or fine-needle aspirates of enlarged lymph nodes or thickened gastrointestinal tissues. Hyphae are observed occasionally, and their morphologic appearance (broad, rarely septate with tapered, rounded ends) in conjunction with a typical inflammatory response can provide a tentative diagnosis of pythiosis, lagenidiosis, or zygomycosis. Microscopic examination of macerated tissue that has been digested in 10% potassium hydroxide may be more likely to reveal hyphal elements than other cytologic specimens.

Histologically pythiosis is characterized by eosinophilic pyogranulomatous inflammation. Affected tissues contain multiple foci of necrosis surrounded and infiltrated by neutrophils, eosinophils, and macrophages. In addition, discrete granulomas composed of epithelioid macrophages, plasma cells, multinucleate giant cells; and fewer neutrophils and eosinophils are often observed. Organisms typically are found within areas of necrosis or at the center of granulomas. Vasculitis is present occasionally. In gastrointestinal pythiosis inflammation centers on the submucosal and muscular layers rather than the mucosa and lamina propria. Therefore the diagnosis of pythiosis may be missed on endoscopic biopsies that fail to reach deeper tissues. Similarly, disease in animals with cutaneous pythiosis typically is found in the deep dermis and subcutis, necessitating deep wedge biopsies rather than punch biopsies for optimal evaluation. *P. insidiosum* hyphae are not visualized routinely on H&E-stained sections but may be identified as clear spaces surrounded by a narrow band of eosinophilic material. Hyphae are readily visualized in sections stained with Gomori's methenamine silver (GMS) but usually do not stain well with periodic acid-Schiff (PAS). *Pythium* hyphae are broad (mean, 4 μ m; range, 2 to 7 μ m), infrequently septate, and occasionally branching (usually at right angles).

Culture

Isolation of *P. insidiosum* from infected tissues is not difficult when appropriate sample handling and culture techniques are used. For best results room temperature (i.e., not refrigerated) tissue samples should be wrapped in a saline-moistened gauze sponge and shipped at ambient temperature to arrive at the laboratory within 24 hours. Small pieces of fresh, nonmacerated tissue should be placed directly on the surface of vegetable extract agar supplemented with streptomycin and ampicillin (or an alternative selective medium) and incubated at 37° C. Growth typically is observed within 12 to 24 hours. Isolation of *P. insidiosum* from swabs of exudate collected from draining skin lesions is generally unsuccessful. Identification of *P. insidiosum* should be based on morphologic features; growth at 37° C; production of motile, biflagellate zoospores; and, if possible, species-specific polymerase chain reaction (PCR) amplification (Grooters and Gee, 2002) or ribosomal ribonucleic acid (rRNA) gene sequencing. Although production of zoospores is an important supporting feature for the identification of pathogenic Oomycetes, it is not specific for *P. insidiosum*. Species-specific PCR amplification can also be used to identify *P. insidiosum* deoxyribonucleic acid (DNA) in fresh, frozen, or paraffin-embedded tissues.

Serology

A highly sensitive and specific enzyme-linked immunosorbent assay (ELISA) for the detection of anti-*P. insidiosum* antibodies in dogs and cats is currently available through my laboratory (Grooters et al., 2002a). In addition to providing a means for early, noninvasive diagnosis, this assay is also very useful for monitoring response to therapy. Following complete surgical resection of infected tissues, a dramatic decrease in antibody levels is typically detected within 2 to 3 months. In contrast, antibody levels remain high in animals that go on to develop clinical recurrence following surgical treatment. In animals treated medically antibody levels change much more slowly, but I have observed significant decreases coincident with clinical improvement within 3 to 4 months of initiating medical therapy for nonresectable disease.

Immunohistochemistry

Several different immunohistochemical techniques have been used previously to confirm the diagnosis of pythiosis. However, the specificity of the antibodies used in these assays has not always been well established. A more recently developed polyclonal anti-*P. insidiosum* antibody raised in chickens and adsorbed with *Lagenidium* and *Conidiobolus* hyphae appears to be highly specific for the immunohistochemical detection of *P. insidiosum* hyphae in tissues. Immunohistochemical staining of tissues for diagnostic purposes using this antibody is available through the author's laboratory.

Therapy

Aggressive surgical resection of all infected tissues is the treatment of choice for pythiosis. In animals with cutaneous lesions confined to a single distal extremity, amputation should be recommended. In patients with gastrointestinal pythiosis segmental lesions should be resected with 3- to 4-cm margins whenever possible. Despite the fact that mesenteric lymphadenopathy is almost always present, *P. insidiosum* hyphae typically are absent in enlarged mesenteric nodes. Therefore the presence of nonresectable mesenteric lymphadenopathy should *not* dissuade the surgeon from pursuing complete resection of a segmental bowel lesion. However, enlarged regional lymph nodes should always be biopsied for prognostic information. Unfortunately most dogs with gastrointestinal pythiosis are not presented to a veterinarian until late in the course of disease, when complete excision is impossible. In addition, the anatomic location of the lesion may prevent complete surgical excision when the esophagus, gastric outflow tract, rectum, or mesenteric root is involved.

Local postoperative recurrence of pythiosis is common (especially when wide surgical margins cannot be achieved) and can occur either at the site of resection or in regional lymph nodes. For this reason medical therapy with itraconazole (10 mg/kg q24h orally [PO]) and terbinafine (5 to 10 mg/kg q24h PO) is recommended for at least 2 to 3 months after surgery. To monitor for recurrence, ELISA serology should be performed before (or within 7 days of) and 2 to 3 months after surgery. In animals that have had a complete surgical resection and have no recurrence of disease, serum antibody levels drop 50% or more within 3 months of

surgery. If this occurs, medical therapy can be discontinued, with optional subsequent reevaluation of serum antibody levels in 2 to 3 months. In my experience surgery is curative in a majority of animals with a distal limb lesion treated with amputation or with a midjejunal lesion that the surgeon believes was completely resected with good margins.

Medical therapy for nonresectable pythiosis is typically unrewarding, likely because ergosterol (the target for most currently available antifungal drugs) is generally lacking in the Oomycete cell membrane. Despite this fact, I have observed clinical and serologic cures in a number of patients treated with a combination of itraconazole (10 mg/kg q24h PO) and terbinafine (5 to 10 mg/kg q24h PO). Although the percentage of animals responding is still quite low (<15%), the combination protocol appears to be superior to itraconazole or amphotericin B alone.

LAGENIDIOSIS

The majority of species in the genus *Lagenidium* are pathogens of insects, crustaceans, algae, and nematodes. The most well-studied species, *Lagenidium giganteum*, is a mosquito larval pathogen that is an Environmental Protection Agency–approved biologic pesticide used for control of mosquito populations. Two morphologically and molecularly distinct species of *Lagenidium* have been isolated from dogs with cutaneous lesions. The first of these species causes uniformly fatal dermatologic and disseminated disease in dogs in the southeastern United States (Grooters et al, 2003). The second pathogenic *Lagenidium* spp. is less common than the first and in dogs is a cause of chronic ulcerative nodular dermatopathy that has a prolonged course and does not appear to extend past local tissues. Although strong antigenic and molecular similarities suggest that the first canine pathogenic *Lagenidium* spp. is closely related to *L. giganteum*, differences in their morphologic and in vitro growth characteristics suggest that they are likely distinct species. Little is currently known about the life cycles of the canine pathogenic *Lagenidium* spp.; however, sporulation and infectivity for these pathogens is likely similar to that associated with *P. insidiosum* and *L. giganteum*. Therefore they would be expected to cause infection via motile aquatic zoospores that adhere to and encyst in damaged tissues.

The epidemiologic features of lagenidiosis that have been identified thus far are similar in many respects to those that have been associated previously with cutaneous pythiosis. Affected animals are typically young to middle-aged dogs living in the southeastern United States. Although most of these dogs have lived in Florida or Louisiana, cases in Texas, Tennessee, Alabama, Georgia, South Carolina, Maryland, Virginia, Indiana, and Illinois have been identified. A number of infected dogs have had frequent exposure to lakes or ponds. None of the affected animals have had historical evidence of immunocompromise or were treated with immunosuppressive therapy before developing the infection. To date lagenidiosis has not been identified in cats.

Clinical Findings

Dogs with *Lagenidium* infection typically are presented for evaluation of progressive cutaneous or subcutaneous lesions (often multifocal) involving the extremities,

mammary region, perineum, or trunk. Grossly these lesions appear as firm dermal or subcutaneous nodules or as ulcerated, thickened, edematous areas of deep cellulitis with regions of necrosis and numerous draining tracts. Hypercalcemia has been associated with *Lagenidium* infection in one dog with cutaneous lesions on all four limbs and severe infection and enlargement of popliteal, inguinal, and prescapular lymph nodes. Similar to the clinical course associated with cutaneous pythiosis, skin lesions in dogs with lagenidiosis tend to be progressive, locally invasive, and poorly responsive to medical therapy.

In dogs infected with the more aggressive species of *Lagenidium*, regional lymphadenopathy is often present and may occur in the absence of obvious cutaneous lesions. Unlike dogs with cutaneous pythiosis, these dogs typically have occult lesions in the thorax or abdomen, including involvement of the great vessels, sublumbar and/or inguinal lymph nodes, lung, pulmonary hilus, and cranial mediastinum. Animals with great vessel or sublumbar lymph node involvement typically have cutaneous or subcutaneous lesions on the hind limbs and often develop hind limb edema. Sudden death caused by great vessel rupture and associated hemoabdomen may occur in these patients.

In dogs infected with the less aggressive species of *Lagenidium*, lesions tend to be locally invasive but rarely extend beyond cutaneous and subcutaneous tissues. Distant lesions in the chest and abdomen have not been identified, and the clinical course appears to be chronic and slowly progressive, with some patients having lesions that progress slowly or are somewhat stable for more than 2 years.

Diagnosis

Because of its clinical, epidemiologic, and histologic similarities to pythiosis, lagenidiosis is often misdiagnosed as pythiosis during routine histologic evaluation. In addition, since many pathologists are more familiar with the Zygomycetes than the Oomycetes, lagenidiosis may also be misdiagnosed as zygomycosis. Although there are subtle differences in hyphal size, morphology, and distribution among these three infections, histologic lesions associated with lagenidiosis are still often labeled as *suspected pythiosis* or *suspected zygomycosis* during routine evaluation. For this reason clinicians should always attempt to follow a suspected histologic diagnosis with serology, culture, immunohistochemical, or molecular confirmation.

Cytology and Histopathology

Cytologic examination of lymph node aspirates or impression smears of draining exudate from dogs with lagenidiosis may reveal pyogranulomatous to eosinophilic inflammation with or without broad, poorly septate hyphal elements. The histologic features of lagenidiosis are similar to those associated with pythiosis and zygomycosis and are characterized by pyogranulomatous and eosinophilic inflammation associated with broad, irregularly branching, infrequently septate hyphae. Multinucleated giant cells and plasma cells commonly are present. In contrast

to *P. insidiosum*, *Lagenidium* spp. hyphae are often visible on H&E-stained sections. On GMS-stained sections numerous broad, thick-walled, irregularly septate hyphae are easily recognized. *Lagenidium* hyphae typically vary greatly in size but in general are larger than *P. insidiosum* hyphae, ranging from 7 to 25 μm in diameter, with an average of 12 μm for the more aggressive species and 7.5 μm for the less aggressive species. In some sections hyphae appear as round or bulbous structures, and occasionally right angle branching is observed. A scant-to-thin eosinophilic sleeve may be noted around the hyphae.

Serology

Immunoblot serology for the detection of anti-*Lagenidium* antibodies in canine serum can provide a presumptive diagnosis of lagenidiosis but must be interpreted in conjunction with results of serologic testing for *P. insidiosum* infection because of the potential for cross-reactivity in serum from dogs with pythiosis. In addition, I have observed nonspecific anti-*Lagenidium* seroreactivity in dogs with other fungal or nonfungal infections, including histoplasmosis and severe pyoderma. Therefore serology alone cannot be used as a basis for the diagnosis of lagenidiosis. However, in the presence of histologic evidence of oomycosis or zygomycosis and the absence of anti-*P. insidiosum* seroreactivity, the identification of anti-*Lagenidium* seroreactivity on immunoblot analysis strongly suggests lagenidiosis. Unfortunately serology is not helpful in differentiating between the two canine pathogenic species of *Lagenidium*.

Culture

The diagnosis of lagenidiosis is best made by culture, which not only provides a definitive diagnosis but is also the only tool currently available for differentiating between the two pathogenic species, which is essential for determining prognosis. Isolation techniques for *Lagenidium* spp. are similar to those described for *P. insidiosum* but with peptone-yeast-glucose agar. For best results small pieces of fresh, nonmacerated tissue should be placed directly on the surface of the agar and incubated at 37°C. Growth typically is observed within 24 to 48 hours. Identification of *Lagenidium* spp. isolates based on morphologic characteristics is more difficult than identification of *P. insidiosum* because zoospores are not as easily produced and because sexual reproductive structures have not yet been identified. Because of the current limitations associated with morphologic characterization, definitive identification of *Lagenidium* spp. should be based on rRNA gene sequencing or genus-specific PCR amplification. This same PCR assay can also be used for the detection of *Lagenidium* DNA in infected tissue samples (Znajda, Grooters, and Marsella, 2002).

Therapy

As with pythiosis, aggressive surgical resection of infected tissues is the treatment of choice for lagenidiosis. When lesions are limited to a single distal extremity, amputation is recommended. In patients with cutaneous lesions in other areas of the body, the surgeon should pursue aggressive resection with wide margins. Since dogs infected with the more aggressive species of *Lagenidium* often have occult systemic lesions, radiographic imaging of the chest and abdomen and sonographic imaging of the abdomen are recommended to determine the extent of disease before attempting surgical resection of cutaneous lesions. Unfortunately the vast majority of dogs infected with this pathogen have nonresectable disease in regional lymph nodes or distant sites by the time the initial diagnosis is made, making the prognosis for these dogs generally grave. In dogs infected with the less aggressive species, surgery that achieves 3-cm margins is often curative. As with pythiosis, medical therapy for lagenidiosis is usually ineffective. However, a combination of itraconazole (10 mg/kg q24h PO) and terbinafine (5 to 10 mg/kg q24h PO) along with repeated aggressive surgical resection was effective in resolving *Lagenidium* infection in one dog with recurrent multifocal cutaneous lesions.

Canine Vaccination Guidelines

RICHARD B. FORD, *Raleigh, North Carolina*

In 2006 the American Animal Hospital Association (AAHA) Canine Vaccine Task Force reconvened to address updates regarding existing vaccines and to review data on new vaccines that have entered the marketplace since the last publication of these recommendations in April 2003. Today the complete text, including references, of the 2006 AAHA Canine Vaccine Guidelines (amended February 2007) is available without restriction at www.aahanet.org (search: Resources/References).

One of the principle reasons stimulating the publication of Guidelines on canine vaccination is the proliferation of licensed vaccines over the past two decades. In the United States alone there are now at least 80 proprietary canine vaccines that include one or a combination of over 25 different antigen types. It is inappropriate to assume that every dog (and every cat) should be inoculated annually against each of the infections for which a vaccine is licensed. Vaccines clearly represent one of the best health care values for animals. Yet, despite the obvious benefits associated with vaccination, there are also risks. Therefore it is the responsibility of veterinarians to acknowledge the fact that vaccination requires a medical decision based on reasonable knowledge of the patient's risk for exposure, life style, and stage of life.

HIGHLIGHTS OF THE 2006 AAHA CANINE VACCINE GUIDELINES

It should be emphasized that the 2006 AAHA Canine Vaccine Guidelines are *recommendations* for the selection and use of canine vaccines in clinical practice. Although the Guidelines represent the most current interpretations of available science, they are not to be construed as dictating an exclusive protocol, course of treatment, or procedure. The decision to implement any part of the published Guidelines is optional. However, the revised Guidelines include information of importance to all practitioners who administer vaccines to dogs. Part 1 of the 2006 Guidelines, entitled Canine Vaccination in the General Veterinary Practice, addresses vaccination recommendations for puppies and adult dogs. These recommendations are summarized in Tables 279-1 and 279-2. Additional topics presented in Part 1 include technologic developments in canine vaccines, vaccine licensing requirements, the role of serologic testing (antibody titers) to assess immunity following vaccination, adverse event recognition and reporting, and medicolegal aspects of vaccination. Recommendations for documenting vaccine administration in the medical record are also addressed. Part 2 of the 2006 Guidelines is new and specifically addresses

recommendations for administering vaccines to shelter-housed dogs. Part 2 will be of particular value to veterinarians who advise shelters on vaccination procedures.

Core Vaccines

Core vaccines are those deemed most important to patient health based on factors related to exposure risk (e.g., parvovirus), severity of disease (e.g., distemper), and transmissibility to humans (e.g., rabies). The Task Force has designated canine distemper virus (CDV), canine parvovirus (CPV), canine adenovirus-2 (CAV-2) (for its ability to protect against canine hepatitis [CAV-1]), and rabies vaccines as core. When feasible, modified-live virus (MLV) vaccines are recommended over killed vaccines. New information on the recombinant canine distemper vaccine has resulted in reclassification of this product as a core vaccine having efficacy that is comparable to MLV distemper vaccines. In addition, the recombinant CDV has been shown to immunize puppies (7 to 9 weeks of age) despite the presence of maternal antibody (Pando et al., 2007). There is no killed CDV vaccine. Killed rabies vaccines, designated 1-year or 3-year vaccines, are the only types available for administration to dogs within the United States and most other countries. The AAHA Canine Vaccine Guidelines on rabies vaccination do not replace or supersede state and/or local statutes.

As outlined in the 2003 AAHA Canine Vaccine Guidelines, a minimum of three doses of core vaccines (CDV, CPV, and CAV-2) should be administered to puppies between 6 and 16 weeks of age. It is emphasized that the final dose be administered at 14 to 16 weeks of age. A subsequent inoculation of the core vaccines should be administered 1 year following administration of the last dose of vaccine in the initial puppy series. Subsequently a single dose (booster) is recommended every 3 years thereafter. Triennial vaccine recommendations apply to *all* of the core vaccines, regardless of manufacturer. Challenge studies involving the MLV core vaccines (CDV, CPV, and CAV-2) have been conducted independently of the manufacturers and have documented the ability of all commercially licensed vaccines to protect dogs against virus challenge for a minimum of 5 years. There is no legal mandate requiring veterinarians to administer a vaccine licensed as a "3-year vaccine" to comply with the AAHA Canine Vaccine Guidelines. A recent study on the duration of immunity derived from vaccination of dogs with the recombinant CDV vaccine also supports a triennial booster recommendation in adult dogs.

Table 279-1

Core Canine Vaccines and Recommendations for Administration

Core Vaccines	Primary Puppy Series (≤ 16 weeks)	Primary Adult Series (> 16 weeks)	Booster Interval
Distemper Recombinant or modified-live	Administer one dose at 6-8 weeks of age and then every 3-4 weeks until 14-16 weeks of age.	Administer two doses 3-4 weeks apart.	Administer one dose 1 year following completion of the initial series and then every 3 years thereafter.
Parvovirus Modified-live			
Adenovirus-2 Modified-live			
Rabies Killed-1 Year Killed-3 Year	Administer one dose at 12-16 weeks of age.	Administer one dose.	Administer one dose 1 year following administration of the first dose and then every 3 years thereafter.

NOTE: Requirements for canine rabies vaccination are established by state and/or local statutes and may differ from the recommendations listed here.

Table 279-2

Noncore Canine Vaccines and Recommendations for Administration

Noncore (Optional) Vaccines	Primary Puppy Series (≤ 16 weeks)	Primary Adult Series (> 16 weeks)	Booster Interval
<i>Bordetella bronchiseptica</i> + Parainfluenza Avirulent-live (intranasal administration ONLY)	A single dose is recommended by the manufacturers and may be given as early as 3-4 weeks of age. Two doses 2-4 weeks apart are suggested for best results. May be given as early as 3-4 weeks of age.	A single dose	Annually; animals in a high risk/exposure environment may benefit from a booster if longer than 6 months since the previous dose.
<i>Bordetella bronchiseptica</i> Killed, or antigen extract	Administer two doses 2-4 weeks apart beginning as early as 8 weeks of age.	Administer two doses 2-4 weeks apart.	Annually; animals in a high risk/exposure environment may benefit from a booster if longer than 6 months since the previous dose.
<i>Leptospira interrogans</i> (Serovars: canicola, icterohaemorrhagiae, pomona, grippityphosa) Various two-way and four-way combinations are available. Killed bacterin	Administer two doses 2-4 weeks apart beginning as early as 12 weeks of age. (Vaccination of dogs less than 12 weeks of age is generally not recommended.)	Administer two doses, 2 to 4 weeks apart.	Annual booster is recommended for dogs with a defined risk of exposure. Vaccination is <i>not</i> recommended for all dogs. Exposure risk should be considered before recommending.
Lyme borreliosis Recombinant or killed bacterin	Administer two doses 2-4 weeks apart beginning as early as 12 weeks of age.	Administer two doses 2-4 weeks apart.	Annual booster is recommended for dogs with a defined risk of exposure. Vaccination is not recommended for all dogs.

NOTE: Unless indicated, all vaccines may be administered by the subcutaneous route.

Noncore or Optional Vaccines

All dogs do not share equal risk of exposure to infectious agents. Principle variables affecting exposure risk include age, breed, health status, life style, geographic location, and travel history. Vaccines classified as noncore are those that a veterinarian may recommend or *not* recommend

based on a reasonable assessment of risk in the individual patient. The 2006 AAHA Canine Vaccine Guidelines have classified the following vaccines as noncore: distemper-measles, all *Bordetella bronchiseptica* vaccines, parainfluenza virus, *Borrelia burgdorferi* (Lyme borreliosis), and *Leptospira interrogans* (all four serovars). The frequency

of administration for noncore vaccines differs depending on the antigen type (avirulent live [topical] versus killed [parenteral]) and the manufacturer's recommendation. When noncore vaccines are indicated for administration in adult dogs, annual administration generally is recommended. Because of the variation among individual products, veterinarians should be familiar with dosing, frequency, and administration requirements of the individual vaccine product selected. Veterinarians are also urged to consult the "Comments and Recommendations" section listed in the summary table of the full text version of the Guidelines (Part 1) to review specific recommendations on administering a particular vaccine type.

Conditionally Licensed Vaccines

Two new canine vaccines, conditionally licensed by the U.S. Department of Agriculture (USDA), are available throughout the United States: *Crotalus atrox* toxoid (western diamondback rattlesnake vaccine) and *Porphyromonas* spp. vaccine (an aid in the prevention of periodontitis). Neither of these vaccines has been subjected to conventional challenge studies. Although a reasonable expectation of efficacy exists, there is currently minimal field validation of efficacy. The AAHA Canine Vaccine Task Force elected not to categorize these vaccines as core, noncore, or "not recommended." Veterinarians considering the use of either of these products are encouraged to review the product literature and, when feasible, the experience offered by colleagues who have experience with the individual product.

Vaccines Not Recommended for Routine Administration

Several vaccine types have been classified by the AAHA Canine Vaccine Task Force as "not recommended." Reasons for assigning such a classification to a particular vaccine include such factors as lack of vaccine efficacy, diminished efficacy compared to alternative antigen types (e.g., killed virus vaccines are expected to be less efficacious than MLV vaccines), and safety. Vaccines classified as "not recommended" are: CAV-1, *Giardia lamblia*, coronavirus (killed virus and MLV), killed CPV, killed CAV-2, and topical (MLV) CAV-2. Each of these vaccines is currently licensed by the USDA and may be selected for administration to dogs at the discretion of the clinician. Veterinarians are encouraged to consult the full text of the 2006 Canine Vaccine Guidelines for additional discussion behind the reason an individual vaccine was given this classification.

GUIDELINES FOR SHELTER-HOUSED DOGS

The frequent introduction of healthy and sick dogs, seasonal variation in population density, and variable risk of exposure among shelter populations make it impractical to define specific "core" vaccine recommendations that will serve all facilities comparably. Only vaccines that are expected to demonstrate a clear benefit against common

and high-threat shelter infections are recommended. The AAHA Canine Vaccine Task Force recognizes the need for individual shelters to tailor vaccination requirements in a manner that is consistent with exposure risk and financial constraints of the individual facility. Because of the high exposure risk faced by shelter-housed dogs, vaccination recommendations made within this section of guidelines are considerably more aggressive than those recommended in general practice.

All dogs should be inoculated with CDV, CPV, and CAV-2 vaccine at the time of entry into the facility. Delaying vaccination by even a few hours could pose significantly increased risk of infection for individual dogs, especially puppies. Vaccines should be MLV; alternatively a recombinant vaccine may be used interchangeably with MLV vaccine for CDV. The recombinant CDV vaccine has the added advantage of immunizing puppies as young as 8 weeks of age even in the presence of passively acquired maternal antibody. With the exception of rabies, killed virus vaccines should not be used in animal shelter vaccination program. When feasible, a single dose of intranasal *B. bronchiseptica* (avirulent live) combined with parainfluenza virus is preferred and should also be administered at the time of entry into the facility. Vaccination is recommended as early as 4 weeks of age (3 weeks of age for intranasal *B. bronchiseptica*), particularly when infection rates within the facility are considered to be high. Vaccines for CDV, CPV, and CAV-2 are repeated every 2 weeks until 16 weeks of age. Dogs over 16 weeks of age should receive a second dose 2 weeks later if still in the facility. A 1-year rabies vaccine is recommended at the time of release from the shelter. Several options for alternative protocols are included in the Guidelines. Individuals seeking detailed information on recommendations for vaccinating shelter-housed dogs should refer to Part 2 of the AAHA Canine Vaccine Guidelines (www.aahanet.org).

Feline Vaccination Guidelines

RICHARD B. FORD, *Raleigh, North Carolina*

In November 2006 the American Association of Feline Practitioners (AAFP) published the latest report of the Feline Vaccine Advisory Panel outlining current feline vaccination recommendations (Richards et al, 2006). This was the first update published since 2000 and provided considerable new information on feline vaccines and vaccination practices. Whether or not an individual veterinarian intends to incorporate the 2006 feline vaccination recommendations into his or her practice, the current document is worthy of review and consideration. In addition to basic recommendations on vaccine administration, the report includes critical information on the selection and use of feline vaccines in practice. As more feline vaccines are introduced, veterinarians have the increasingly complex task of ensuring that individual patients are vaccinated against diseases that pose a *realistic* threat to the individual animal's health yet avoid the risk of adverse reactions associated with vaccination.

There can be little argument that routine vaccination programs remain an exceptional health care value for pets today. Yet the proliferation of new vaccines and new vaccine technology give emphasis to the fact that all vaccines are not necessarily alike. Likewise all cats do not share the same level of risk for exposure to infectious pathogens. It is the objective of the AAFP Feline Vaccine Advisory Panel to develop a document that will facilitate the efforts of practitioners in developing rational vaccination protocols for feline patients. As written, the Advisory Panel's report is not intended to represent a universal protocol applicable for all cats, nor is it intended to represent the standard of care by which all cats must be vaccinated. Although certainly there is no requirement for individual practices to implement the recommendations in the report, this document does contain important, relevant information pertaining to the routine selection and use of feline vaccines in clinical practice. The entire report is available at www.aafponline.org, (search: Practice Guidelines).

HIGHLIGHTS OF THE 2006 AAFP FELINE VACCINE GUIDELINES

The 2006 Report of the AAFP Feline Vaccine Advisory Panel is the most comprehensive review of feline vaccines and vaccination programs yet published. The report is comprehensive and includes 14 separate sections that address topics such as basic vaccine immunology, the types of vaccines available today, and recommendations on routes of vaccine administration. The report also includes a number of special considerations that pertain directly to the administration of vaccines in cats such as age, breed, and vaccination intervals. Additional special

considerations include administration of vaccine to cattery cats, lactating queens, sick cats, retrovirus-infected cats, cats receiving corticosteroids, and cats having a prior history of vaccine-associated adverse reactions (events). Updated information on controversial topics such as the extended duration of immunity for the feline (core vaccines) and the triennial booster recommendations is also presented. Of importance to all practitioners is the section on legal considerations, which centers on liability associated with vaccinating cats. Topics on vaccine standards of care and informed consent are also presented.

The section on vaccine adverse events, also called adverse reactions, highlights the exceptional safety record of vaccines yet outlines concerns over the lack of available data for the types of reactions that are believed to occur. Much of the discussion addresses vaccine-associated fibrosarcomas, perhaps the single most important vaccine adverse event that occurs in companion animal medicine. Veterinarians in the United States are encouraged to report feline vaccine adverse events, known or suspected, to the Center for Veterinary Biologics (CVB, www.aphis.usda.gov/vs/cvb) online and to the vaccine manufacturer (manufacturers are required to forward reports to the CVB).

One noteworthy addition to the report is the section on vaccination of shelter-housed cats. This section complements information found in the 2006 American Animal Hospital Association (AAHA) Canine Vaccine Guidelines, which is available on the AAHA website available at www.aahanet.org (also see Chapter 279). Furthermore, new recommendations on the vaccination of cats in trap-neuter-return programs and kitten socialization classes are included. The report also includes six appendices that focus on issues ranging from vaccination site recommendations to vaccine handling and storage requirements.

Core Vaccines

For several years the primary vaccination series for kittens has been a single dose administered at 9 and 12 weeks of age. The current guidelines, however, recommend that the first dose of core vaccines (feline parvovirus [panleukopenia virus], herpesvirus-1, and calicivirus) be administered as early as 6 weeks of age and then every 3 to 4 weeks until 16 weeks of age. This should be followed by a booster at 1 year of age and every 3 years thereafter. A rabies vaccine, also recommended as core for all cats, can be administered as a single dose as early as 12 weeks of age; a booster is administered 1 year later. State or local rabies ordinances that dictate different requirements have precedence over any recommendations published in the 2006 AAFP Feline Vaccine Advisory Panel Report (Tables 280-1 and 280-2).

Table 280-1

Core Feline Vaccines and Recommendations for Administration

Core Vaccines	Primary Kitten Series (≤16 weeks)	Primary Adult Series (>16 weeks)	Booster Interval
Parvovirus (Panleukopenia)			
Herpesvirus-1 and calicivirus Modified-live (nonadjuvanted) or killed (adjuvanted) (subcutaneous or intranasal administration)	Administer one dose as early as 6 weeks of age and then every 3-4 weeks until 16 weeks of age.	Administer two doses 3-4 weeks apart.	Administer one dose 1 year following completion of the initial series and then every 3 years thereafter. NOTE: It is still appropriate to recom- mend annual booster against feline herpesvirus-1 and feline calicivirus for cats housed in high risk environments.
Rabies Recombinant (nonadjuvanted)	Administer one dose at 12-16 weeks of age.	Administer one dose.	Annually
Rabies Killed: 1 year Killed: 3 year (adjuvanted)	Administer one dose at 12-16 weeks of age.	Administer one dose.	Administer one dose 1 year following administration of the first dose and then every 3 years thereafter.

NOTE: Requirements for feline rabies vaccination are established by state and/or local statutes and may differ from the recommendations listed here.

Table 280-2

Noncore Feline Vaccines and Recommendations for Administration

Noncore (Optional) Vaccines	Primary Kitten Series (≤16 weeks)	Primary Adult Series (>16 weeks)	Booster Interval
Feline Leukemia Recombinant (nonadjuvanted) (transdermal administration <i>only</i>)	Administer two doses 3-4 weeks apart beginning as early as 12 weeks of age.	Administer two doses 3-4 weeks apart.	Annual booster; booster vaccination is <i>not</i> recommended for all cats. Exposure risk should be considered before recommending.
Feline Leukemia Killed (adjuvanted)	Administer two dose 3-4 weeks apart beginning as early as 12 weeks of age.	Administer two doses 3-4 weeks apart.	Annual booster; booster vaccination is <i>not</i> recommended for all cats. Exposure risk should be considered before recommending.
<i>Chlamydomphila felis</i> Avirulent live (nonadjuvanted)	Administer two doses 3-4 weeks apart beginning as early as 12 weeks of age.	Administer two doses 3-4 weeks apart.	Annual booster; booster vaccination is <i>not</i> recommended for all cats. Exposure risk should be considered before recommending.
<i>Chlamydomphila felis</i> Killed (adjuvanted)	Administer two doses 3-4 weeks apart beginning as early as 12 weeks of age.	Administer two doses 3-4 weeks apart.	Annual booster; booster vaccination is <i>not</i> recommended for all cats. Exposure risk should be considered before recommending.
Feline Immunodeficiency Virus Killed (adjuvanted)	Administration of three initial doses is required. Beginning as early as 8 weeks of age, administer two additional doses 2-3 weeks apart.	Administration of three initial doses is required. Each dose should be administered 2-3 weeks apart.	Annual booster; booster vaccination is <i>not</i> recommended for all cats. Exposure risk should be considered before recommending. NOTE: A single dose of feline immuno- deficiency virus (FIV) vaccine can result in a false-positive test result on all commercial FIV tests for at least 1 year.
Bordetella bronchiseptica Avirulent live (nonadjuvanted) (intranasal <i>only</i>)	Administer a single dose as early as 8 weeks of age.	Administer a single dose.	Administer annually, but only in cats with established risk of exposure.

NOTE: Routine vaccination of cats against feline infectious peritonitis virus and *Giardia lamblia* is *not generally recommended*. Unless otherwise stipulated, all feline vaccines should be administered by the subcutaneous route.

Feline Leukemia Virus Vaccine

Feline leukemia virus (FeLV) vaccine continues to be listed as noncore. However, since kittens are more likely than adults to become persistently viremic following exposure, the Advisory Panel highly recommends that all kittens receive a two-dose primary series, beginning as early as 8 weeks of age, and a booster 1 year after completion of the initial series. There are no published studies documenting vaccine duration of immunity beyond 1 year. Therefore adults deemed to be at sustained risk of exposure (e.g., outdoor cats) should be vaccinated annually. Documentation of a negative FeLV (antigen) test is recommended before administration of the FeLV vaccine.

Vaccination of Retrovirus-Positive Cats

Studies evaluating the ability of FeLV- and feline immunodeficiency virus (FIV)-infected cats to mount a protective immune response subsequent to vaccination vary. However, it is the recommendation of the Advisory Panel that feline core vaccines should be administered to healthy, retrovirus-positive cats. It is left to the discretion of the clinician whether the risk of exposure in an individual cat justifies vaccine administration. There is no known therapeutic value in administering either an FeLV or FIV vaccine to a retrovirus-infected cat.

Adjuvanted versus Nonadjuvanted Feline Vaccine

Based on the finding of several published studies, the association between adjuvanted vaccine use and the development of vaccine-associated fibrosarcomas is deemed to be sufficiently compelling that the Advisory Panel recommends that “veterinarians use less inflammatory products whenever possible.” Avoiding adjuvanted vaccines is not a guarantee that an individual cat will never develop cancer at an injection site; however, simply recommending that injectable vaccines be administered as low (distal) on the leg as feasible to facilitate amputation remains an impractical solution to the vaccine-associated sarcoma problem. At this writing, all feline killed virus and killed bacterial vaccines contain adjuvant. Modified-live virus, avirulent live bacteria (e.g., intranasal administration), and recombinant vaccines do not contain adjuvant.

Vaccination Against Feline Immunodeficiency Virus

Particularly important is the fact that a single dose of the FIV vaccine can result in the production of antibodies that cause (false)-positive test results on all commercially available FIV tests. Vaccine-induced antibodies can also be passed from queen to kittens via colostrum and interfere with testing beyond the age of weaning. FIV test interference in adult vaccinated cats has been shown to persist for at least 1 year. In kittens test interference derived from ingestion of colostrum appears to wane by 12 weeks of age. Cats receiving the current FIV vaccine should be permanently identified (e.g., microchip).

Vaccines Not Recommended for Routine Administration

Consistent with recommendations published in 2000, the Advisory Panel continues to stipulate that vaccination of cats against feline coronavirus (FCoV), to prevent feline infectious peritonitis (FIP) infection, and *Giardia lamblia* is “not generally recommended.” Although considerable controversy surrounds the ability of the FIP vaccine to protect cats from infection, most studies have shown little or no benefit from routine inoculation. The *G. lamblia* vaccine contains chemically inactivated (killed) trophozoites and an adjuvant. In independent studies administration of this vaccine did not lessen cyst shedding in experimentally infected cats when compared with control cats.

Virulent Systemic Feline Calicivirus Vaccine

In January 2007 a killed, adjuvanted vaccine was licensed in the United States as an aid in preventing infection with virulent systemic feline calicivirus (VS-FCV). Earlier a bivalent, killed (nonadjuvanted) calicivirus vaccine was licensed in the United Kingdom. Neither of these vaccines was addressed in the 2006 Advisory Panel Report. An amendment to the report addressing recommendations on the use of the VS-FCV vaccine is expected later in 2008. VS-FCV is a highly contagious, severe infection that occurs predominantly in adult cats; most reports involve cats residing in shelters. At least one outbreak has been documented in a veterinary hospital housing shelter cats. However, in the last decade fewer than 10 outbreaks have been documented in the United States and United Kingdom combined. Vaccine efficacy has been demonstrated in cats experimentally challenged with a calicivirus strain that was homologous with the virus strain used in the vaccine. However, the literature currently does not support the ability of a single VS-FCV strain to provide cross-protection against VS-FCVs that may be encountered in cats in future outbreaks. This vaccine is neither a replacement for nor an alternative to the combined calicivirus vaccine plus feline herpesvirus-1 administered to cats for the prevention of viral upper respiratory infections.

VACCINATION OF SHELTER-HOUSED CATS

Vaccination of cats presented to and maintained in a shelter-type environment presents a number of unique and challenging issues to veterinarians attempting to manage morbidity and limit mortality associated with contagious infectious diseases, particularly panleukopenia, herpesvirus-1, and calicivirus infection. In general, the Advisory Panel recommends that all cats receive vaccine against panleukopenia, herpesvirus-1, and calicivirus on entry to the facility; a 1-year rabies vaccine is administered at the time of release. There are no indications for administration of FeLV, FIV, *G. lamblia*, and *Bordetella bronchiseptica* vaccine in the shelter environment. One exception for consideration includes vaccination of kittens against FeLV when housing requirements dictate that unrelated kittens be housed together. For specific recommendations on individual vaccines, the full text of the 2006 Feline Vaccine Guidelines should be consulted.

CHAPTER 281

Feline Leukemia Virus and Feline Immunodeficiency Virus

KATRIN HARTMANN, *Munich, Germany*

The three feline retroviruses, feline immunodeficiency virus (FIV), feline leukemia virus (FeLV), and feline foamy virus (FeFV), are global and widespread. Although all three viruses are in the family Retroviridae, they differ in their potential to cause disease. FeFV (previously known as feline syncytium-forming virus, FeSFV), a spumavirus, is not associated with disease; thus routine testing is not performed.

FIV, a lentivirus that shares many properties with human immunodeficiency virus (HIV), can cause an acquired immune deficiency syndrome in cats, with increased risk for opportunistic infections, neurologic diseases, and tumors. In most naturally infected cats FIV infection does not cause a severe clinical syndrome, and with proper care FIV-infected cats can live many years. Many in fact die at an older age from causes completely unrelated to FIV infection. In a study of naturally FIV-infected cats, the rate of progression was variable, with death occurring in about 18% of infected cats within the first 2 years of observation (about 5 years after the estimated time of infection). An additional 18% developed increasingly severe disease, but more than 50% remained clinically asymptomatic during the 2 years of observation (Levy et al., 2000). FIV infection has little impact on a cat population, and does not reduce the number of cats in a household. Thus overall survival time is not necessarily

shorter than in uninfected cats, and quality of life is usually fairly high over an extended period of time.

FeLV, an oncornavirus, is the most pathogenic of the three viruses. Historically it was considered to account for more disease-related deaths and clinical syndromes than any other single infectious agent in cats. More recently the prevalence and consequently the importance of FeLV as a pathogen in cats have been decreasing, mainly because of testing and eradication programs and the relatively common use of FeLV vaccines. The death rate of persistently viremic cats in multicat households is approximately 50% in 2 years and 80% in 3 years but is lower in cats kept strictly indoors in single-cat households. Despite the fact that persistent FeLV viremia is associated with a decrease in life expectancy, many owners elect to provide treatment for the clinical syndromes that accompany infection. With proper care, many FeLV-infected cats kept indoors only may live for many years with good quality of life.

A decision for treatment or for euthanasia of a cat should never be based solely on the presence of a retrovirus infection. FIV- and FeLV-infected cats are subject to the same diseases that befall cats free of those infections, and illness in a given cat may not be related to the retrovirus infection at all. However, in all cats, healthy or sick, FIV and FeLV status should be known because retrovirus infection impacts health status and long-term patient management.

MANAGEMENT OF RETROVIRUS-INFECTED MULTICAT HOUSEHOLDS

When a cat in a multicat household is diagnosed with a retrovirus infection, all cats in that household should be tested to determine their virus status. If positive and negative cats are identified within the same household, the owner must be informed of the potential danger to uninfected cats and told that the best method of preventing spread of infection is to isolate the infected individuals and prevent them from interacting with housemates. However, despite this admonition, the overall risk of transmission between these cats is not very high for either infection.

FIV transmission in households with a stable social cat environment is rare because FIV is mainly transmitted through biting and fighting; if no fights occur, FIV will not be transmitted. In long-term studies of households with FIV-infected cats, few additional cats became FIV positive over time; in some households no transmission occurred over many years. All cats in these households should be neutered, and it is crucial not to introduce a new cat into the household since this might lead to fights and to transmission, even between cats that have lived together peacefully for a long time.

The benefit of FIV vaccination of FIV-negative cats in households with an FIV-positive cat is controversial (see Chapter 280). The vaccine currently available has not been tested under these conditions. Usually the FIV subtype of the infected cat is unknown, and cross-protection by the vaccine against some FIV subtypes (e.g., the frequently found subtype B) is uncertain. Because the vaccine contains whole virus, cats respond to vaccination by producing antibodies that are indistinguishable from those produced during natural infection. Therefore *all vaccinated cats will be antibody positive*, and assessment of their true infection status can be difficult. Ideally, before vaccination is considered the veterinarian should ensure that the virus in the infected cat can be detected by polymerase chain reaction (which is only possible in 50% to 80% of cases). Only if the virus strain of the infected cat is detectable by PCR will it be possible to later identify another cat in the household that might become infected despite vaccination.

If an FeLV-infected cat has lived for some time in an otherwise FeLV-negative household, the other cats that have been together with the FeLV-infected cat will already have been infected. Thus, these cats are most likely immune to new infection, and an owner may elect to keep all of the cats together. However, studies in cluster households have shown that virus-neutralizing antibodies do not persist for life; thus a previously immune cat may become viremic. This may be the result of new infection or reactivation of a long-persisting latent infection. The risk of infection in adult FeLV-negative cats is approximately 10% to 15% if they have lived with a viremic cat for several months. If owners refuse to separate housemates, the *uninfected cats should receive FeLV vaccination* to enhance their natural level of immunity. However, owners should be informed that vaccination does not provide sufficient levels of protection in these environments of high viral exposure. If the household is closed to new cats, the FeLV-negative cats tend to outlive the infected cats.

MANAGEMENT OF INDIVIDUAL RETROVIRUS-INFECTED CATS

The most important life-prolonging advice the veterinarian can advance to owners of retrovirus-infected cats is “keep the cats strictly indoors”. This not only avoids spread to other cats in the neighborhood, but also prevents exposure of the immunosuppressed, retrovirus-infected cat to infectious agents carried by other animals. In FIV-infected cats, secondary infections not only cause clinical signs but also may lead to progression of the FIV infection itself. This is probably not the case in FeLV infection in which the retroviral infection itself is more pathogenic and progresses relatively independently of cofactors.

“Routine vaccination” of retrovirus-infected cats is subject to much discussion. It is the recommendation of an Advisory Panel on Feline vaccination that feline core vaccines should be administered to healthy, retrovirus-positive cats at risk (see Chapter 280 for details). The author’s recommendations follow.

While there is no scientific proof that retrovirus-infected cats are at increased risk from modified-life virus (MLV) vaccines, inactivated vaccines are recommended out of concern that MLV vaccines given to immune-suppressed animals may regain pathogenicity. FIV-infected cats are susceptible to secondary infection (thus regular vaccination would seem indicated). Studies have shown that healthy FIV-infected cats are able to mount appropriate levels of protective neutralizing antibodies after vaccination. However, it is the author’s opinion that vaccines should not be given to FIV-infected cats, if strictly kept indoors because not only immune suppression, but also immune stimulation, can lead to progression of FIV infection by altering the balance between the immune system and the virus. Stimulation of FIV-infected lymphocytes is known to promote virus production *in vitro*. *In vivo* vaccination of chronically infected FIV-infected cats with a synthetic peptide was associated with a decrease in the CD4/CD8 ratio. Thus the potential tradeoff to protection from infection with vaccination is progression of FIV infection secondary to increased virus production. If FIV-infected cats are kept strictly indoors, the risk of secondary infections is lower than the possible adverse effects of vaccination. It should be noted that in some countries or states legal requirements for rabies vaccination may supersede these issues.

The author, however, agrees with the recommendation that FeLV-infected cats should be administered routine vaccinations. In studies of immune response to rabies vaccination, it was demonstrated that FeLV-infected cats may not be able to mount adequate immune responses. Therefore protection in an FeLV-infected cat after vaccination is not comparable to that in a healthy cat, and more frequent vaccinations than usually recommended must be considered (e.g., every 6 months), especially in cats that are allowed to go outside in areas with high rabies prevalence.

Retrovirus-infected cats should have veterinary evaluations at least semiannually to promptly detect changes in health status. A complete blood count (CBC), biochemistry profile, and urinalysis should be performed at least annually

(CBC every 6 months in FeLV-infected cats to detect anemia or other cytopenias associated with FeLV infection). Intact male and female retrovirus-infected cats should be neutered to reduce stress associated with estrus and mating behavior and the desire to roam outside the house or interact aggressively. Surgery is generally well tolerated by asymptomatic retrovirus-infected cats, but perioperative antibiotic administration should be used for all surgeries and dental procedures. Since the viruses live for only minutes outside of the host and are susceptible to all disinfectants (including common soap), simple precautions and routine cleaning procedures will prevent transmission in the hospital. Retrovirus-infected cats can be housed in the same ward as other hospitalized patients; however, they should be housed in individual cages. They may be immune suppressed and should be kept away from cats with other infectious diseases. Under no circumstances should they be placed in a "contagious disease ward" with cats suffering from infections such as viral respiratory disease.

If retrovirus-infected cats are sick, prompt and accurate identification of the secondary illness is essential to allow early therapeutic intervention and a successful treatment outcome. Therefore more intensive diagnostic testing should proceed earlier in the course of illness than might be recommended for uninfected cats. Many cats with retrovirus infection respond as well as uninfected cats to appropriate medications, although a longer or more aggressive course of therapy (e.g., antibiotics) may be needed. Corticosteroids or other immune-suppressive or bone marrow-suppressive drugs should be avoided. Griseofulvin has been shown to cause bone marrow suppression in FIV-infected cats and should not be used.

Recombinant human granulocyte colony-stimulation factor (rHuG-CSF; Filgastrim) is contraindicated in neutropenic FIV-infected cats. Although it increases neutrophil counts, treatment can also lead to a significant increase in viral load in peripheral blood mononuclear cells by enhancing infection of lymphocytes or increasing expression of FIV by infected lymphocytes. Until data in FeLV-infected cats are available, rHuG-CSF therapy also cannot be recommended.

Recombinant human erythropoietin (rHuEPO) may be effective in cats with nonregenerative anemia. FIV-infected cats treated with HuEPO (100 units/kg subcutaneously [SQ] q48h) showed a gradual increase in red and white blood cell counts, and increases in viral loads were not observed; thus rHuEPO appears to be safe in FIV-infected cats. No studies are available for FeLV-infected cats, but the author assumes rHuEPO will have the same positive effects.

Recombinant human insulin-like growth factor-1 (rHuIGF-1) can induce thymic growth and stimulate T cell function. Treatment with rHuIGF-1 resulted in a significant increase in thymus size and thymic cortical regeneration replenishing the peripheral T cell pool in experimentally FIV-infected cats. It could be considered in young FIV-infected cats as supportive treatment, but there are no field studies so far to show its effect in naturally FIV-infected cats. Its usefulness in FeLV infection is also unknown.

IMMUNE MODULATOR THERAPY

Immune modulators or interferon inducers are widely used in retrovirus-infected cats, especially FeLV-infected cats

(Table 282-1). Although reports of uncontrolled studies frequently suggest sometimes dramatic clinical improvement, these effects generally have not been reproduced in properly controlled studies. It has been suggested that these agents may benefit infected animals by restoring compromised immune function, thereby allowing the patient to control viral burden and recover from the disease. Most reports in the veterinary literature are difficult to interpret because of vague diagnostic criteria, lack of clinical staging or follow-up, small numbers of cats studied, absence of a placebo-treated control group, the natural variability of the course of disease, and the fact that additional supportive treatments were administered. Especially the homeopathic remedies have not been sufficiently evaluated in feline retrovirus infections and these drugs cannot be recommended.

In FeLV-infected cats every immune modulator therapy should be considered very carefully. There is no conclusive evidence from controlled studies that immune modulators or alternative drugs have any beneficial effects on health or survival of asymptomatic or symptomatic FIV-infected cats. As suggested previously, nonspecific stimulation of the immune system might even be contraindicated in FIV infection because it can lead to an increase in virus replication caused by activation of latently infected lymphocytes and macrophages. Thus nonspecific immunomodulators with unknown effects are not recommended in FIV-infected cats.

A number of immune modulators have been used against FeLV infection. Pind-avi (parapox virus avis) and pind-orf (parapox virus ovis) are inactivated poxviruses that belong to the so-called *paramunity inducers*. Their suggested mode of action is primarily induction of interferons and activation of natural killer cells. These compounds caused a sensation in Germany when it was published that their administration resulted in a cure of 80% to 100% of FeLV-infected cats, even those in moribund condition. Paramunity inducers (1ml SQ twice a week for 6 weeks) quickly became the most commonly used treatment for FeLV infection in Europe. However, two placebo-controlled, double-blind trials (including 120 and 30 cats, respectively) using the same treatment protocol in naturally FeLV-infected cats under controlled conditions failed to reproduce these striking results. There were no significant differences between the cats treated with paramunity inducers and placebo-treated cats in the number of cats that terminated viremia or in any clinical, laboratory, immunologic, or virologic parameter investigated (Hartmann et al., 1998). These studies demonstrate the importance of sufficiently controlled clinical trials in the assessment of novel therapies for feline retrovirus infections.

Acemannan, a water-soluble, long-chain complex carbohydrate polymer derived from the aloe vera plant, is thought to be taken up by macrophages, stimulating them to release cytokines, which in turn stimulate cell-mediated immune responses, including cytotoxicity. In one uncontrolled trial, 50 cats with natural FeLV infection were treated with acemannan (2mg/kg intraperitoneally [IP] once a week for 6 weeks). After 12 weeks 71% of the cats were known to be alive, all cats remained FeLV antigen positive, and no significant change was noted in their clinical signs or hematologic parameters. There was no control group; thus assessment of the results is difficult (Sheets et al., 1991).

Table 281-1

Treatment Options for Retrovirus-Infected Cats

Drug		Efficacy in vitro?	Controlled Studies in vivo?	Efficacy in vivo?	Author Opinion on Use
Antiviral Drugs					
Zidovudine	FIV	Yes	Yes	Yes	Effective in some cats
	FeLV	Yes	Yes	No	Not effective in field cats
Stavudine	FIV	Yes	No	n.d.	Possibly effective
	FeLV	n.d.	No	n.d.	Possibly effective
Didanosine	FIV	Yes	No	n.d.	Possibly effective
	FeLV	Yes	No	n.d.	Possibly effective
Zalcitabine	FIV	Yes	No	n.d.	Toxic in high dosages
	FeLV	Yes	Yes	No	Toxic in high dosages
Lamivudine	FIV	Yes	Yes	No	Toxic in high dosages
	FeLV	No	No	n.d.	Toxic in high dosages
Ribavirin	FIV	Yes	No	n.d.	Toxic in cats
	FeLV	Yes	No	n.d.	Toxic in cats
Foscarnet	FIV	Yes	No	n.d.	Toxic
	FeLV	Yes	No	n.d.	Toxic
Suramin	FIV	n.d.	No	n.d.	Likely ineffective
	FeLV	n.d.	No	n.d.	Likely ineffective
T20	FIV	No	No	No	Ineffective
	FeLV	n.d.	No	n.d.	Likely ineffective
AMD3100	FIV	Yes	Yes	Yes	Some effect in field cat
	FeLV	n.d.	No	n.d.	Likely ineffective
Lactoferrin	FIV	n.d.	Yes	±	Possibly effective in stomatitis
	FeLV	n.d.	No	n.d.	Possibly effective in stomatitis
Human interferon- α	FIV	Yes	No	n.d.	Likely ineffective
	subcutaneous high dose	FeLV	Yes	No	Ineffective
	oral low dose	FIV	No	±	Improved survival
	FeLV	Yes	Yes	No	Ineffective
Feline interferon- ω	FIV	Yes	Yes	No	Ineffective
	FeLV	Yes	Yes	±	Improved survival
Immune Modulators					
Polyriboinosinic-polyribocytidylic acid	FIV	n.d.	No	n.d.	Contraindicated
	FeLV	n.d.	No	n.d.	Likely ineffective
Pind-avi/Pind-orf	FIV	n.d.	No	n.d.	Contraindicated
	FeLV	n.d.	Yes	No	Ineffective
Acemannan	FIV	n.d.	No	n.d.	Contraindicated
	FeLV	n.d.	No	n.d.	Likely ineffective
<i>Staphylococcus</i> protein A	FIV	n.d.	No	n.d.	Contraindicated
	FeLV	n.d.	Yes	±	Possibly effective
<i>Propionibacterium acnes</i>	FIV	n.d.	No	n.d.	Contraindicated
	FeLV	n.d.	No	n.d.	Likely ineffective
Bacille Calmette-Guérin (BCG)	FIV	n.d.	No	n.d.	Contraindicated
	FeLV	n.d.	Yes	No	Ineffective
<i>Serratia marcescens</i>	FIV	n.d.	No	n.d.	Contraindicated
	FeLV	n.d.	Yes	No	Ineffective
Levamisole	FIV	n.d.	No	n.d.	Contraindicated
	FeLV	n.d.	No	n.d.	Likely ineffective
Diethylcarbamazine	FIV	n.d.	No	n.d.	Contraindicated
	FeLV	n.d.	Yes	No	Ineffective
Nosodes	FIV	n.d.	No	n.d.	Contraindicated
	FeLV	n.d.	No	n.d.	Likely ineffective

FeLV, Feline leukemia virus; FIV, feline immunodeficiency virus; n.d., not determined; ±, some effect.

Staphylococcus protein A (SPA), a bacterial polypeptide purified from cell walls of *Staphylococcus aureus* Cowan I, can bind to the Fc portion of certain immunoglobulin G subclasses by a nonimmunologic mechanism without disturbing antigen binding and may combine with immune

complexes; stimulate complement activation; and induce T cell activation, stimulation of natural killer cells, and interferon production. A variety of SPA sources and treatments have been used in FeLV-infected cats. In some studies a high rate of tumor remission and conversion to

FeLV-negative status was observed; in others responses were less dramatic and short lived. However, in an experimental study that included kittens with experimental FeLV infection, SPA treatment neither reversed anemia nor improved humoral immune function. In a placebo-controlled study, treatment of ill client-owned FeLV-infected cats with SPA (10mcg/kg twice weekly for up to 10 weeks) did not cause a statistically significant difference in FeLV status, survival time, or clinical and hematologic parameters when compared with a placebo-treated control group; but it did result in significant improvement in the owners' subjective impression of the health of their pets (McCaw et al., 2001).

Propionibacterium acnes, formerly *Corynebacterium parvum*, is a killed bacterial product that stimulates macrophages and the release of various cytokines and interferons and enhances T cell and natural killer cell activity in mice. It has been used in FeLV-infected cats (0.2mg/cat intravenously [IV] twice a week and then once a week for at least 6 weeks), but no prospective studies have been performed, and anecdotal reports note that about 50% of the treated cats improved. A number of other immunostimulants, including a cell wall extract of a nonpathogenic strain of *Mycobacterium bovis* (Bacille Calmette-Guérin), extracts of *Serratia marcescens*, levamisole, and diethylcarbamazine, have not shown any efficacy in altering virus production or immune function in properly performed (controlled) studies despite in vitro evidence of immunomodulatory effects.

ANTIVIRAL CHEMOTHERAPY

Most antivirals used in cats are licensed for humans and are intended specifically for treatment of HIV infection. Some can be used to treat FIV infection because most enzymes of FIV and HIV have similar sensitivities to various inhibitors. However, few controlled studies have been performed to support their use in cats. Nucleoside analogs are usually less effective against FeLV when compared to FIV because FeLV is not as closely related to HIV.

Zidovudine, 3'-azido-2',3'-dideoxythymidine (AZT), is a nucleoside analog (thymidine derivative) that blocks the reverse transcriptase of retroviruses and inhibits new infections of cells. AZT can inhibit FIV replication in vitro and in vivo, reduce plasma virus load, improve the immunologic and clinical status of FIV-infected cats, increase quality of life, and prolongs life expectancy. In a placebo-controlled trial, AZT improved stomatitis in naturally infected cats. It should be used at a dosage of 5 to 10mg/kg every 12 hours orally or subcutaneously. The higher dose should be used carefully since side effects can develop. For subcutaneous injection the lyophilized product should be diluted in isotonic NaCl solution to prevent local irritation. For oral application syrup or gelatin capsules (with dosage individualized for the cat) can be used. During treatment a CBC should be performed regularly (weekly for the first month) because nonregenerative anemia is a common side effect, especially if the higher dosage is used. If blood values are stable after the first month, a monthly check is sufficient. Cats with bone marrow suppression should not be treated with AZT. Studies in which FIV-infected cats were treated for 2 years showed that AZT is well tolerated. Some cats may develop a mild decrease of hematocrit initially in the first 3 weeks that resolves

even if treatment is continued. If hematocrit drops below 20%, discontinuation is recommended, and anemia usually resolves within a few days. Unfortunately, as in HIV, AZT-resistant mutants of FIV can arise as early as 6 months after initiation of treatment. AZT is also effective against FeLV in vitro. When treated less than 1 week after experimental inoculation, cats were protected from FeLV bone marrow infection and persistent viremia. However, in a study with naturally FeLV-infected cats, 6 weeks of treatment with AZT did not lead to a statistically significant improvement of clinical, laboratory, immunologic, or virologic parameters. In general, therapeutic efficacy of AZT in FeLV-infected cats seems to be less promising than in cats infected with FIV. It should be used only at low dosage (5 mg/kg orally [PO] or SQ q12h) in FeLV-infected cats because of its bone marrow-suppressive effects.

Several other nucleoside analogs with a similar mode of action to that of AZT and licensed for treatment of HIV-infected patients have activity against feline retroviruses. The in vitro and in vivo activity of these drugs against FIV and FeLV is summarized in Table 286-1.

Foscarnet is a pyrophosphate analog that reversibly inhibits virus-specific deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) polymerase and reverse transcriptase by binding to the enzymes at a site distinct from that of nucleoside analogs. It has a wide spectrum of activity against DNA and RNA viruses. In vitro foscarnet has activity against FIV and FeLV, but no reliable data exist on its in vivo efficacy in cats, and its use in cats is limited because of toxicity. It is nephrotoxic and myelosuppressive and chelates cations such as calcium, so that hypocalcemia, hypomagnesemia, and hypokalemia may develop. Foscarnet is toxic to epithelial cells and mucous membranes, leading to severe gastrointestinal side effects and ulceration of genital epithelium.

Suramin, a sulfated naphthylamine, has been used primarily as an antiparasitic. It is also effective against several viruses through inhibition of reverse transcriptase by interacting with the template-primer binding site of the enzyme that is necessary for DNA prolongation. However, it is also associated with severe side effects, including nausea and anaphylactic shock (during administration), peripheral neuritis, agranulocytosis, hemolytic anemia, and destruction of the adrenal cortex. No reliable studies exist to show its effect against FIV. Suramin was used to treat FeLV-infected cats, although only a limited number of cats were studied. FeLV-related anemia improved in these cats, and serum viral infectivity ceased transiently. However, because these studies were not controlled, results must be interpreted carefully, and the severe side effects limit its use in cat patients.

T20 is a new anti-HIV drug that inhibits virus entry by inhibiting fusion of the virus with the cell membrane. It has been tested against several retroviruses, including FIV, but showed minimal antiviral effect likely because of insufficient sequence homology of the primary amino acid sequence of HIV and FIV in the critical regions. It has not been tested against FeLV but is likely ineffective. AMD3100 belongs to the new class of bicyclams that act as selective antagonists of the chemokine receptor CXCR4. CXCR4 is the main coreceptor for T cell-line-adapted HIV strains, and blocking the CXCR4 receptor leads to inhibition of virus entry. FIV also uses CXCR4 for virus entry,

and a high degree of homology exists between the human and feline CXCR4. AMD3100 is not licensed as an antiviral compound but as a stem cell activator for patients that undergo bone marrow transplantation. It is effective against FIV in vitro; and in a placebo-controlled double-blind study in which 40 naturally FIV-infected cats were treated with AMD 3100 (0.5 mg/kg q12h SQ for 6 weeks) it caused a statistically significant improvement in clinical signs and decreased the proviral load in FIV-infected cats without side effects. AMD3100 has not been tested against FeLV but is likely ineffective because FeLV uses different receptors for virus entry into the cell.

Lactoferrin is a mammalian iron-binding glycoprotein that has antibacterial, antifungal, antiprotozoal, and antiviral properties. Antiviral activity may occur as a result of lactoferrin interaction with the viral receptors on the cell surface or by direct neutralization or inhibition of the viral particle. Lactoferrin is produced by mucosal epithelial cells of many mammalian species and is present in secretions such as tears, milk, saliva, seminal or vaginal fluids, and low concentrations in plasma. Side effects are not described. Lactoferrin had some effect in cats with stomatitis, and it may be an option for treatment of FIV- and FeLV-related stomatitis.

Human interferon- α has immune-modulatory effects but also acts as a true antiviral compound by inducing a general antiviral state of cells that protects them against virus replication (also see Chapter 85). Two common treatment regimens are used in cats: subcutaneous injection of high-dose interferon (10^4 to 10^6 units/kg q24h), or oral application of a low-dose treatment (1 to 50 units/kg q24h). Measurable serum levels can be obtained when given subcutaneously, but using this regimen it becomes ineffective after 3 to 7 weeks because of development of neutralizing antibodies. Human interferon- α given orally is not absorbed but is destroyed in the gastrointestinal tract; no measurable serum levels develop. The only way oral interferon may have an effect is by stimulation of the local lymphoid tissue in the oral cavity. In murine studies it was shown that subcutaneous administration of interferon- α had an antiviral effect, whereas oral administration only caused immunomodulation. In a recent study a positive effect on the survival of FIV-infected cats could be demonstrated using low-dose oral human interferon- α . Human interferon- α inhibits FeLV replication in vitro and has been used in several studies in FeLV-infected cats. Treatment with high dosages of subcutaneous human interferon- α (1.6×10^4 and 1.6×10^6 units/kg SQ) in experimentally FeLV-infected cats with high levels of persistent antigenemia resulted in significant decreases in circulating FeLV p27 antigen. However, as a result of anti-interferon- α antibody development, cats became refractory to therapy after 3 or 7 weeks. In a study of naturally FeLV-infected cats, high-dose subcutaneous treatment with human interferon- α (1×10^5 units/kg SQ q24h for 6 weeks) did not lead to a statistically significant improvement of clinical, laboratory, immunologic, or virologic parameters. In an experimental placebo-controlled study, low-dose oral interferon- α (0.5 units/cat or 5 units/cat PO) did not lead to a difference in the development of viremia when treatment started directly after challenge, although treated cats had significantly fewer clinical signs and longer survival times when compared to the placebo group (with a

better response using 0.5 units/cat). In a recent placebo-controlled study including ill client-owned FeLV-infected cats that were treated with low-dose oral interferon- α (30 units/cat q24h for 7 consecutive days on a 1-week-on/1-week-off schedule), there were no statistically significant differences in FeLV status, survival time, clinical or hematologic parameters or subjective improvement in the owners' impression of clinical signs.

Feline interferon- ω recently was licensed for use in veterinary medicine in some European countries and Japan. Interferons are species-specific; therefore feline interferon- ω can be used for prolonged periods without antibody development. No side effects have been reported in cats. Feline interferon- ω is active against FIV in vitro, but to date only one study has been performed in field cats, and the study did not show significant changes in survival rate when compared to a placebo group. Feline interferon- ω also inhibits FeLV replication in vitro. In a placebo-controlled field study, 48 cats with FeLV infection were treated with interferon- ω (10^6 units/kg SQ q24h on 5 consecutive days repeated three times with several weeks between treatments). A statistically significant difference was found in the survival time of treated versus untreated cats (De Mari et al., 2004). However, no virologic parameters were measured during the study to support the hypothesis that the interferon actually had an anti-FeLV effect rather than an inhibition of secondary infections, and further studies are needed. A summary of reported experimental treatments is found in Table 286-1.

Feline Calicivirus Infection

JANE E. SYKES, *Davis, California*

Feline calicivirus (FCV) is a common cause of feline upper respiratory tract disease (URTD), accounting for anywhere between 20% and 53% of cases. Infection may be manifested by fever, conjunctivitis, rhinitis, oral ulcerations, and/or chronic stomatitis, although occasionally skin ulcerations, lameness, and pneumonia may occur. The severity and signs of illness depend on the strain of FCV involved, the infecting dose, and the degree of host immunity.

FCV is a nonenveloped, single-stranded ribonucleic acid (RNA) virus with a spheric capsid studded with cup-shaped depressions. Like other RNA viruses, the genome of FCV continually undergoes rapid mutation with minimal rates of repair, increasing the diversity of strains over time.

Cats that recover from URTD may develop a persistent oropharyngeal infection with continuous shedding of virus from this site, although the magnitude of shedding varies over time and among individual cats. In many cats shedding terminates weeks to months after infection, but in a few cats shedding is lifelong. Some cats appear never to shed virus. Because of the carrier state, the prevalence of FCV infection in the general cat population is high, ranging from 8% to 47%, depending on the density of the cat population sampled. A single cat may be infected with multiple variants of FCV at the same time, each derived from the original infecting strain as a result of genetic mutation, drift, and selection pressures (Radford et al., 1998).

URTD caused by FCV is a problem especially in cats residing in multiple-cat households and breeding and boarding catteries. Although the introduction of vaccines targeting FCV in the mid 1970s may have reduced the severity of clinical signs, the vaccines do not prevent infection or persistent shedding of FCV, and outbreaks of URTD still occur, even in well-vaccinated cat populations. Vaccine virus itself may be shed from the oropharynx, and virus closely related to the F9 vaccine strain has been detected in cat colonies that are chronically shedding FCV. There has been some concern that vaccine pressure may have led to selection of FCV strains that have poor cross-reactivity with the vaccine strain F9, and incorporation of additional strains into vaccines has been proposed (Dawson et al., 1993).

Over the last 5 years several highly virulent strains of FCV have been isolated from outbreaks of a systemic, febrile illness in North American cats. This condition was described initially in northern California (Pedersen et al., 2000) and subsequently in several other American states (Rong et al., 2006). Most recently it has been described in the United Kingdom (Coyne et al., 2006). The disease has

been termed *FCV-associated virulent systemic disease (VSD)*, and in some outbreaks has been associated with mortalities of up to 67%. Furthermore, vaccination with currently available FCV vaccines apparently has not been protective. The purpose of this chapter is to discuss the clinical signs, epidemiology, diagnosis, control, and treatment of FCV infections, with particular emphasis on the recently reported outbreaks of VSD.

EPIDEMIOLOGY

Infection with FCV may be acquired by direct contact with an acutely infected cat, organisms persisting within the environment, or a carrier cat. FCV is shed primarily in oral, nasal, and ocular secretions and can also be found in blood, urine, and feces of infected cats. Transmission over distances of about 4 feet may occur via droplets generated by sneezing cats.

FCV-associated VSD was first described in northern California in 1998 (Pedersen et al., 2000). Death occurred in 33% to 50% of infected cats, and this strain was highly contagious, spreading via contaminated fomites despite implementation of aggressive disinfection measures. A novel FCV strain, FCV-Ari, was isolated from affected cats. Laboratory cats experimentally infected with FCV-Ari developed a disease syndrome identical to that seen in naturally infected cats. Since FCV-Ari was described, at least five additional outbreaks have been recognized in Pennsylvania, Massachusetts, Tennessee, Nevada, and southern California; and in 2003 an outbreak of systemic caliciviral disease occurred in Staffordshire, England (Coyne et al., 2006). FCV-Kaos, a genetically distinct strain from FCV-Ari, was isolated from cats in the southern California outbreak (Hurley et al., 2004), and the strains isolated in the Massachusetts (FCV-Diva) and United Kingdom (UKOS) outbreaks also have been genetically distinct. This may suggest that the mutation(s) associated with VSD are different in each case or that these mutations occurred in a part of the FCV genome that was not sequenced.

In the majority of outbreaks a hospitalized shelter cat appeared to be the source of infection. Three outbreaks involved a single veterinary hospital, one spread to a veterinary research facility in the course of the outbreak investigation, and the largest reported outbreak affected 54 cats in three veterinary practices and a rescue group in the west Los Angeles area from June to August, 2002 (Hurley et al., 2004). The spread of this southern California outbreak was attributed to the travel of clients and staff between multiple practices located within a 1-mile radius. With the exception of the United Kingdom

outbreak, which involved two neighboring households, spread of disease was limited to the affected clinic(s) or shelter, with no spread within the community reported. Otherwise healthy, adult, vaccinated cats were affected predominantly, whereas kittens tended to show less severe signs. In all cases the outbreaks resolved within approximately 2 months. Two outbreaks occurred in the spring, three in the summer, and two in the fall. No outbreak has yet been reported in winter, a time when the kitten population is lowest, reflecting the possible role of kittens in the generation and transmission of virulent FCV strains.

Transmission of the virulent FCV strains occurs readily through fomite transmission via veterinary hospital staff and pet owners, by movement of clinically and subclinically infected cats between clinics and private homes, and by indirect contact of outpatients with subclinically infected inpatients.

An epidemiologic analysis of the outbreak that occurred in southern California showed that adult cats (>1 year old) were at significantly higher risk than kittens (<6 months old) for severe disease or death (odds ratio 9.56, $p < 0.001$) (Hurley et al., 2004). No sex or breed predilection was noted. The attack rate for cats hospitalized for ≥ 12 hours concurrently with an infected cat or from the same household as a case cat was 94%. In one study four kittens orally immunized with the current vaccine strain (F9) experienced less severe clinical signs when experimentally infected with FCV-Ari, but vaccination did not appear to prevent severe disease or death in the FCV-Kaos outbreak (Pedersen et al., 2000). The surviving cats in the United Kingdom outbreak had been vaccinated more recently than the nonsurvivors (Coyne et al., 2006).

As with other FCV infections, cats infected with highly virulent strains may shed virus for months after infection (Hurley et al., 2004). Despite these observations, there has been no report of transmission of the VSD from recovered cats. Loss of the virulence-enhancing mutation(s) may have occurred during passage in these cats; alternatively, implementation of effective control measures may have played a role in outbreak resolution.

CLINICAL SIGNS

Acute URTD caused by FCV occurs after an incubation period of 2 to 10 days. Typical signs of URTD include serous or mucopurulent nasal and ocular discharge, sneezing, conjunctival hyperemia, blepharospasm, and chemosis. Depression, anorexia, hypersalivation, and pyrexia also may be seen; and occasionally pneumonia may develop with coughing and dyspnea. Lameness, which may reflect polyarthritis, can be seen in infected cats. Ulcerative glossitis develops in some affected cats, and a small proportion of FCV carriers develop chronic lymphoplasmacytic or ulceroproliferative stomatitis, which may be refractory to treatment.

Cats exposed to FCV strains causing VSD have developed signs 1 to 5 days after exposure to affected cats. The incubation period has been longer (up to 12 days) for some cats exposed in the home environment (Hurley et al., 2004). Affected cats frequently show signs typical of caliciviral URTD, including anorexia, oral ulceration, and nasal and/or ocular discharge; these signs are often severe.

Pyrexia is present in most cases and may be profound, often exceeding 105°F. Distinctive clinical signs of VSD include peripheral edema with or without alopecia, crusting, and ulceration. Edema is most commonly noted on the head and limbs; and crusting and ulceration, if present, are most prominent on the nose, lips, pinnae, periocular skin, and distal limbs. Some cats may be reluctant to walk. Severe respiratory distress, sometimes caused by pulmonary edema or pleural effusion, develops in some cats. Dysphonia was reported in several cats in the United Kingdom outbreak. Icterus has been noted in many cats, and the presence of jaundice and dyspnea has been associated with a poor prognosis. Involvement of the gastrointestinal tract, including the liver and pancreas, may be associated with signs of vomiting and/or diarrhea. Rarely epistaxis and hematochezia have been noted. Peracutely affected cats may die suddenly with few preceding signs except fever. Overall mortality in the VSD cases has been approximately 50%.

DIAGNOSIS

The clinical signs resulting from uncomplicated FCV infection can result from infection with other agents, especially feline herpesvirus 1 but also bacterial pathogens such as *Chlamydia felis* and *Bordetella bronchiseptica*. Thus clinical signs alone are not useful for establishment of a definitive diagnosis, although the presence of severe oral ulcerations and/or lameness may be suggestive of FCV infection. Mixed-pathogen infections are common in cattery situations, further complicating diagnosis. Cats presenting with signs of epistaxis, unilateral nasal discharge, facial deformity, fundic abnormalities, or marked submandibular lymphadenopathy should receive a thorough workup to rule out other causes of URTD such as neoplasia, nasopharyngeal polyps, coagulopathy, foreign bodies, dental disease, and cryptococcosis. Although clinical signs of VSD are more characteristic, conditions such as cryptococcosis, feline infectious peritonitis, and immune-mediated vasculitides represent possible differential diagnoses.

Clinicopathologic abnormalities resulting from infection with less virulent FCV strains are generally nonspecific. Hyperglobulinemia may be noted in cats with chronic stomatitis. In contrast, infection with highly virulent strains may result in clinicopathologic abnormalities, reflecting damage to multiple organ systems (Hurley et al., 2004). Frequently reported serum chemistry profile abnormalities include mild-to-moderate hyperbilirubinemia, hypoalbuminemia, hyperglycemia, elevated creatine phosphokinase and aspartate aminotransferase activity, and mildly elevated alanine aminotransferase activity. Abnormalities on the complete blood count have included lymphopenia, mild-to-moderate neutrophilia, and mild anemia.

Necropsy findings in VSD cases are variable. In addition to icterus, cutaneous edema, and ulceration, which are apparent grossly, the most common pathology finding has been individual or centrilobular hepatocellular necrosis (Coyne et al., 2006; Pesavento et al., 2004). Other reported abnormalities have included acute bronchointerstitial pneumonia, pancreatic necrosis and saponification

of peripancreatic fat, splenic and lymphoid necrosis, and free pleural and abdominal fluid. Intestinal crypt lesions were reported in four experimentally infected and one naturally infected cat (Hurley et al., 2004; Pedersen et al., 2000). Gastrointestinal ulceration has been reported occasionally. Viral antigen has been detected in both endothelial and epithelial cells in affected tissues, with epithelial cell cytolysis and associated systemic vascular compromise (Pesavento et al., 2004). Ideally a full necropsy should be performed whenever VSD is suspected. At minimum, tissues to examine include skin (particularly footpads, nasal planum, and any areas of ulceration), tongue, lung, liver, spleen, gastrointestinal tract, pancreas, and lymph nodes.

Attempts to make a specific diagnosis in cases of URTD are especially encouraged in cattery situations because knowledge of the causative organism can assist with management strategies. Diagnostic evaluation is also recommended for individual cats that do not respond to conventional symptomatic treatment or those that experience recurrent episodes of URTD. Because of the communicability and high mortality associated with highly virulent FCV infection, microbiologic testing is essential for cats suspected to have VSD, and suspect cats should be treated and handled immediately as if they were infected with hypervirulent FCV.

The most reliable microbiologic assay for FCV is virus isolation from nasal, conjunctival, and/or oropharyngeal swabs after inoculation of cell monolayers grown in the laboratory. Oropharyngeal swabs are most likely to yield a diagnosis; although, if possible, collection of nasal and conjunctival swabs, in addition to oropharyngeal swabs, increases the chance of obtaining a positive result. Swabs should be transported on ice in a viral transport medium containing antibiotics to prevent bacterial overgrowth; commercial swabs are available for this purpose.

Virus isolation from oropharyngeal swabs collected from acute cases of VSD or tissue samples obtained at necropsy has had high sensitivity (>90%). Positive culture results were also obtained on serum samples from acutely ill cats, although the sensitivity was lower than with culture from oropharyngeal swabs. Sensitivity of viral culture on oropharyngeal swabs decreases rapidly in recovering cats, and a single negative swab taken more than a week after onset of clinical signs does not rule out infection with FCV. At least two to three negative cultures should be obtained at weekly intervals before concluding that virus shedding is likely to have terminated.

In general, serology is not recommended for routine diagnosis of FCV infections. Because of widespread exposure to FCV, acute and convalescent phase samples are required to demonstrate recent infection. Titers induced by vaccination can confound diagnosis; and, because of the large numbers of FCV strains, titers may vary, depending on the degree of homology between the infecting virus and the FCV strain used in the assay. Nevertheless, in the case of FCV strains causing VSD, serology using virus neutralization has been sensitive and specific and was useful for investigation and control of the southern California outbreak (Hurley et al., 2004). There was no cross-neutralization between the vaccine (F9) strain and FCV-Kaos or FCV-Ari; thus identification of unexposed cats even in the

face of recent vaccination may be possible. Whether this will be true for other hypervirulent strains (and thus for other outbreaks) awaits further investigation.

Amplification of FCV nucleic acid using the reverse-transcriptase polymerase chain reaction (RT-PCR) represents another diagnostic assay that may be considered for diagnosis. Compared with those for deoxyribonucleic acid viruses such as feline herpesvirus 1, PCR-based assays for FCV are less reliable because of the difficulty in designing assays that amplify nucleic acid from a variety of different strains and the susceptibility of viral RNA to rapid degradation by RNase enzymes in the environment. False-positive results associated with contamination can occur during sample collection or in the laboratory. Current PCR-based assays for FCV are generally only available in research laboratories, and quality control may vary from laboratory to laboratory and even between individual staff members working in the same laboratory. Therefore the results of PCR-based testing should be interpreted with caution. In the southern California outbreak of VSD, all isolates recovered in culture were successfully amplified using RT-PCR (Hurley et al., 2004).

Regardless of the method used to detect FCV infection, the results of diagnostic testing should always be interpreted in the light of clinical signs because asymptomatic cats may shed FCV. The same applies for FCV strains associated with VSD; because there have been no consistent molecular differences identified between highly virulent strains and other strains of FCV, it is not possible to identify an isolate as a VSD strain using molecular typing methods. Positive identification of an outbreak requires that a molecularly distinct strain of FCV be isolated and sequenced from at least two affected cats in association with the appearance of consistent clinical signs. Once an outbreak has been identified in this manner, nucleic acid sequencing may be useful for determining whether additional FCV isolates obtained in the outbreak have the potential to cause VSD (because of their relation to the original isolates) or whether they represent unrelated field FCV or vaccine strains. Because subclinically infected cats are capable of transmitting VSD, all exposed cats, whether symptomatic or not, should be checked by viral culture or RT-PCR before being introduced to naïve cats.

TREATMENT

Treatment of disease resulting from FCV infection is symptomatic. Broad-spectrum antimicrobials (e.g., amoxicillin, 22 mg/kg orally [PO] q12h; or doxycycline, 10 mg/kg PO q24h) may be required to counteract secondary bacterial infection. Fluid and nutritional support is essential in severe cases, and airway humidification should also be considered. Placement of esophagostomy or gastrostomy tubes allows enteral nutrition of cats with inappetence. Oxygen may be required for cats with pneumonia.

In addition to the treatments described in the previous paragraph, cats with VSD should be placed in isolation and treated aggressively with colloid-containing fluids such as Hetastarch (Hespan, Baxter; Deerfield, IL). A variety of different treatments have been tried, including a wide range of broad-spectrum antibiotics and oral interferon- α . Glucocorticoids at immunosuppressive doses

(1 mg/kg PO q12h) have also been used. In the outbreak in southern California five severely affected cats were treated with dexamethasone (in addition to other supportive treatments) and survived; one cat that was treated with prednisone died, but the remaining cats that died did not receive glucocorticoids (Hurley and Sykes, 2003). One cat in the northern California outbreak lived following glucocorticoid treatment; the remainder were not treated with steroids.

RECOMMENDATIONS FOR CONTROL

Although outbreaks can be devastating within an affected clinic or shelter, VSD remains extremely uncommon. Quick recognition and implementation of effective control measures, including proper disinfection, quarantine, and testing procedures, will further reduce the impact of this disease.

Recognizing that VSD may be spread even by mildly symptomatic cats (especially kittens), veterinarians should exercise careful infectious disease control whenever dealing with a cat with URTD. FCV is reliably inactivated by sodium hypochlorite (in the absence of organic matter and with adequate contact time) but not by other compounds commonly used for disinfection in veterinary hospitals such as chlorhexidine or quaternary ammonium compounds. Therefore routine decontamination after exposure to a cat with upper respiratory infection should be to clean with a detergent solution and then disinfect with 5% sodium hypochlorite diluted with water to 1:32 (½ cup of 5% bleach per gallon of water). In the absence of effective disinfection, FCVs reportedly can persist in a dried state at room temperature (20°C) for up to 28 days (Doultree et al., 1999). Therefore effective cleaning and quarantine are crucial. Specific control measures recommended when VSD is diagnosed or strongly suspected include strict isolation of suspect cases, isolation of exposed cats for at least 2 weeks after exposure, ensuring that exposed or infected

cats are not shedding virus before release into environments containing naïve cats, and thorough disinfection with 5% bleach solution or heat sterilization. Carpeted areas/homes should be steam cleaned and closed to cats for a minimum of 4 weeks. Clinics in which disease continues to spread despite instituting these precautions should consider closing to cat admissions for 1 to 2 weeks. If recently vaccinated cats are less severely affected in any outbreak, vaccination of naïve cats with a modified-live vaccine at least 1 to 2 weeks before potential exposure may be helpful, although it should be recognized that vaccination with a modified-live vaccine may result in positive test results using virus isolation.

Babesiosis

ADAM J. BIRKENHEUER, *Raleigh, North Carolina*

One of the earliest descriptions of intraerythrocytic parasites in dogs with signs consistent with babesiosis was made in 1896, and the first documented case of canine babesiosis in the United States was reported in 1934. Initially there were only two species of *Babesia* believed to infect dogs; however, at the time of this writing, there are at least nine genetically unique piroplasma that have been identified in the blood of dogs (Table 283-1).

EPIZOOTIOLOGY

Piroplasma are intraerythrocytic protozoan parasites of the phylum Apicomplexa that are frequently transmitted by ticks. Piroplasma include organisms in the families Babesiidae and Theileridae. *Babesia* spp. are distinguished from *Theileria* spp. by the absence of any preerythrocytic stage in the mammalian host. In contrast, *Theileria* spp. first infect leukocytes (typically lymphocytes) before the organisms infect erythrocytes. Babesiosis was the first documented tick-transmitted infection, demonstrated by Smith and Kilbourne in 1888. They demonstrated that “Texas fever” was transmitted by ticks in cattle and that the causative agent was believed to be either *Babesia bigemina* or *Babesia bovis*. Over 100 species of *Babesia* have since been described, and with the advent of molecular techniques such as the polymerase chain reaction (PCR) many new species and genotypes are identified each year. Although many vertebrate species can be infected with two or more of the known *Babesia* spp., this chapter focuses on canine piroplasmosis.

TRANSMISSION AND RISK FACTORS

The primary route of transmission for piroplasma is believed to be via a tick vector. The known or suspected tick vectors for each piroplasma are listed in Table 283-1. The recent emergence of some piroplasma such as *Babesia gibsoni* is likely to be associated with nontick-associated routes of transmission. In North America the majority of *B. gibsoni* transmission appears to be among American pit bull terriers and is associated with transplacental infection and direct inoculation via dog bites. Cases of *B. gibsoni* in dogs that were not of this breed were frequently bitten by an American Pit Bull terrier or received a transfusion with blood donated by a dog of that breed. However, more *B. gibsoni* cases are being identified in other canine breeds within the United States, without these exposure to these known risk factors. Breed associations and risk factors for infection are listed in Table 283-1.

CLINICAL DISEASE

The disease manifestations of canine piroplasma infection are highly variable. Multiple factors are responsible for the differences in pathogenicity, including the genotype/species of piroplasm, individual host immune responses, and age and possibly breed of the host. Classic canine piroplasmosis is characterized by anemia, thrombocytopenia, hyperglobulinemia, fever that may wax and wane, and splenomegaly. These findings are fairly consistent in most cases regardless of geographic region, genotype of piroplasm, or host. Hemoglobinemia is a relatively rare finding in dogs in North America and is most commonly documented in dogs in South Africa. In at least one study 85% of dogs with piroplasmosis had Coombs'-positive test results. Thus piroplasmosis should be considered as a differential diagnosis for all dogs presenting with immune-mediated hemolytic anemia (IMHA) and or thrombocytopenia. In highly endemic areas, for dogs with a history of known risk factors for piroplasmosis or for dogs of a breed known to be at high risk for piroplasmosis, empiric antiprotozoal therapy (see following paragraphs) should be started immediately after samples are obtained for specific testing.

There are no pathognomonic biochemical or urinalysis findings in dogs with piroplasmosis. The most consistent biochemical findings include hyperglobulinemia and less commonly hyperbilirubinemia with mildly increased liver enzymes. Some dogs present for pigmenturia consisting most commonly of bilirubin and occasionally hemoglobin.

There are recognized differences in the virulence of the different species/genotypes of piroplasms that infect dogs (see Table 283-1). *Babesia canis rossi*, which has only been documented in southern Africa, is considered highly virulent and has been associated with severe disease manifestations such as disseminated intravascular coagulation, central nervous system signs and hypoglycemia, and in some cases death. *Babesia canis vogeli* has a nearly worldwide distribution and is typically considered the least virulent. *Babesia canis canis* is considered to have virulence intermediate to *B. canis rossi* and *B. canis vogeli* and is recognized primarily in Europe, with the majority of cases having been reported in France. *B. gibsoni* is a small piroplasm (1 to 3 μ m) that is rapidly emerging and seems to now have a nearly worldwide distribution. *B. gibsoni* is considered a moderately virulent piroplasma. A *Babesia microti*-like parasite, formerly referred to as *Theileria annae*, has been recently recognized in Spain. In addition to the classic signs associated with piroplasmosis, this organism has been associated with renal failure and proteinuria,

Table 283-1

Overview of Canine Piroplasmosis

Genotype/Species	Distribution	Vector	Risk Factors	Virulence	Treatment	Parasite Clearance With Treatment
<i>Babesia canis vogeli</i>	Worldwide	<i>Rhipicephalus sanguineus</i>	Greyhounds, ticks, blood transfusion	+	Imidocarb dipropionate (6.6 mg/kg IM q2 weeks)	Y

presumably caused by glomerular disease. *Babesia conradae*, originally believed to be *B. gibsoni*, is a highly virulent parasite and is associated with high mortality rates. It is important to note that all species have caused severe disease manifestations in individual patients; thus the guidelines for virulence may not be strictly clinically relevant. However, it is important that the clinician accurately identify the species/genotype infecting the individual patient because the prognosis and treatment for each species can vary.

"Atypical" presentations of canine piroplasma infection appear to be becoming more common. The most common atypical presentations include thrombocytopenia and hyperglobulinemia without anemia, thrombocytopenia alone, hyperglobulinemia alone, and the complete absence of hematologic or biochemical abnormalities. The reasons behind these atypical presentations are not clearly understood, but possible causes include parasite adaptations to canine hosts resulting in decreased virulence, increased clinician vigilance and willingness to test, spontaneous recovery, and alternative routes of

transmission that may be associated with decreased virulence (direct inoculation or transplacental transmission).

DIAGNOSIS

The diagnosis of piroplasmosis in the clinical setting can be quite challenging. Several factors can increase the clinician's index of suspicion such as breed (greyhounds have increased prevalence of *B. canis vogeli*, and American Pit Bull terriers have increased prevalence of *B. gibsoni* infections), history of a dog bite, blood transfusion, or tick attachment. Three basic methods are available to diagnose piroplasmosis: light microscopy, serology, and nucleic acid-based detection methods. Unfortunately the clinical sensitivity and specificity of most of the available tests are unknown; but clinical experience, case series and reports, and limited studies performed on experimentally infected dogs have demonstrated that all modalities can have either false-positive or false-negative results.

When performed by an experienced reader, light microscopy is highly specific for the presence of piroplasmosis,

but, because of the relatively low limit of detection (0.001% parasitemias), the sensitivity is poor; thus it is not recommended as a sole screening test. In addition, several species/genotypes are virtually indistinguishable by light microscopy, making accurate identification to the species/genotype level nearly impossible. Serologic detection of anti-*Babesia* antibodies, which is almost always performed in commercial laboratories by the use of indirect fluorescent antibody (IFA) assays, is considered to be fairly sensitive as a screening test. Since serology only provides indirect evidence of infection and is well documented to have false-negative results in some clinical cases, it is the responsibility of the clinician to interpret the results in light of the clinical presentation and the response to treatment. Despite the fact that IFA assays are available for several different genotypes, the ability of these assays to accurately differentiate the species/genotype actually causing a given infection is relatively poor (i.e., the highest titer does not always correlate to which species is present). It is for these reasons that nucleic acid based testing is quickly becoming an important component to the diagnosis of canine babesiosis.

PCR assays are the primary molecular method used by commercial diagnostic laboratories. PCR is generally accepted to have increased sensitivity compared to light microscopy, and in some cases the limit of detection is 1300 times lower. The overall sensitivity of one assay for the diagnosis of chronic *B. gibsoni* infections was 90% over three different testing periods. The assay detected infection in 100% of studied dogs when two consecutive tests were performed. Although this improved sensitivity is important, it is the exquisite specificity of PCR (>99.9% when the proper controls are used) that give it outstanding clinical usefulness. A positive result from a reputable laboratory is consistent with infection and should identify the specific species/genotype so appropriate therapeutic decisions can be made. The major clinical concern for PCR assays is the lack of assay standardization among laboratories and the marked variability in sensitivity and specificity (differences of limits of detection ≥ 1000 fold) with different assay design, reaction protocols, controls, and reagents. Therefore it is critical that clinicians contact individual laboratories and get specific information about each assay and the controls used for proper interpretation of test results. Ultimately in some cases a multifaceted approach that includes microscopy, serology, and PCR may be necessary to maximize the chances of diagnosing *Babesia* infections.

TREATMENT AND PREVENTION

Significant improvements in the availability and types of treatments for canine babesiosis have been made. In highly endemic areas or in breeds with increased risk of infection, therapy should be started as soon as possible and is often administered empirically based on clinical suspicion. Specific therapies for canine piroplasmosis are presented in Table 283-1. Based on our clinical experience, treatment with atovaquone (Mepron, GlaxoSmithKline) and azithromycin is effective and capable of clearing *B. canis vogeli* infections but is

considerably more expensive than imidocarb dipropionate (Imizol, Schering-Plough). A combination formulation of atovaquone with proguanil hydrochloride (Malarone, GlaxoSmithKline) is less expensive, but it is poorly tolerated by dogs, with substantial vomiting as an adverse effect. Imidocarb and the less widely available diminazene aceturate are both capable of inducing remission of clinical signs in dogs with *B. gibsoni* infection, but neither treatment is successful at clearing the infection. Their use in *B. gibsoni* infections is warranted when atovaquone and azithromycin are unavailable or the cost of treatment is prohibitive.

The clinical signs associated with piroplasmosis typically begin to improve within 1 week of beginning specific therapy. If patients are not responding to specific therapy, secondary treatments should be administered, or alternative diagnoses should be considered. Since the anemia and thrombocytopenia associated with piroplasmosis are often immune mediated, immunosuppressive therapy is frequently considered as an adjunctive therapy. If piroplasmosis is highly suspected or definitively identified, I recommend only supportive care and antiprotozoal therapy. It is my experience that prolonged immunosuppressive therapy (i.e., weeks to months) or splenectomy before treatment with specific antiprotozoal drugs substantially reduces the ability to clear the parasitemias and subsequently is associated with a worse prognosis because of relapsing disease. In addition, many dogs with secondary IMHA and immune mediated thrombocytopenia purpura have responded to antiprotozoal drugs alone and have not required additional treatments. Clinical signs should resolve in most cases within 5 to 7 days of beginning antiprotozoal treatment. If immunosuppressive treatment must be instituted, prednisone alone (2 mg/kg/day) is usually sufficient and can be tapered more quickly (every 2 weeks versus every 3 to 4 weeks) compared to protocols for the treatment of idiopathic IMHA. Follow-up testing should consist of at least two consecutive negative PCR tests approximately 30 days apart.

The best approach to the prevention of piroplasmosis has not been established, but several logical strategies have been proposed. In France a vaccine composed of an adjuvant and soluble antigens collected from supernatants of *B. canis* cultures is available. This vaccine induces partial protection (i.e., less severe clinical disease) but does not prevent infection and has only been demonstrated to be efficacious against *B. canis*. The avoidance of risk factors (see Table 283-1) is likely to result in reduced infection rates. The use of topical acaricides is likely to result in reduced infection rates, assuming that the agents either repel ticks or actually block the transmission. To date there are no data evaluating the efficacy of topical acaricides for the prevention of piroplasmosis, but their use in highly endemic areas is probably warranted based at least on the theoretic advantages. Finally, blood donors should be screened aggressively for the presence of *Babesia* infections before their entry into a donor program and periodically if they have potentially been infected between screening and donation (e.g., ticks, volunteer donors that are indoor/outdoor).

CHAPTER 284

Canine Influenza

GABRIELE A. LANDOLT, *Fort Collins, Colorado*
KATHARINE F. LUNN, *Fort Collins, Colorado*

Influenza is a well-known and highly contagious disease that has burdened humans, poultry, horses, and pigs since ancient times. Before 2004 dogs were not commonly regarded as hosts for influenza A viruses. Since then canine influenza has been recognized as a recently emerged respiratory pathogen in dogs in the United States. First isolated from racing greyhounds in Florida, the virus has since spilled over into the nongreyhound dog population and has caused outbreaks of respiratory disease throughout the United States.

ETIOLOGY

Canine influenza is primarily a respiratory disease caused by an influenza A virus. Influenza A viruses are members of the family Orthomyxoviridae and are enveloped viruses with segmented, single-stranded, negative-sense ribonucleic acid genomes. Based on antigenic properties of the two major envelope glycoproteins, hemagglutinin (HA) and neuraminidase (NA), influenza A viruses are further classified into 16 HA (H1-H16) and 9 NA (N1-N9) subtypes. The viruses exhibit only partial restriction of their host range, and occasionally influenza viruses or their genes are transferred between species. Undoubtedly the most prominent examples of direct transmission of influenza viruses among species are the recent infections of humans and cats with the highly pathogenic avian H5N1 viruses ("bird flu"). Yet, although cross-species transmission of influenza viruses may occur relatively frequently, these transmission events tend to be self-limiting; and the

newly introduced viruses are only rarely maintained in the new host species. One of the few notable exceptions to this scenario is the recent transmission of an equine-lineage H3N8 virus to dogs in the United States, with apparent maintenance of the virus within the dog population. In the spring of 2004, 22 racing greyhounds housed at a training facility in Florida suffered from a severe respiratory illness that was characterized by cough and high fever. Eight of the affected dogs died from hemorrhagic pneumonia, and influenza A virus was recovered from the lung tissue of one animal. Sequence analysis of the viral genome revealed that the canine isolate was closely related to, and had evolved from, a contemporary equine H3N8 influenza virus. Over the course of that same year, outbreaks of influenza occurred at 14 greyhound racetracks in six states, and by 2005 the virus had spilled over into the nongreyhound dog population.

Recent reports from researchers in the United Kingdom provide data supporting two additional independent incidents in which equine influenza viruses have been transmitted to dogs. When alerted to the canine influenza outbreak in the United States, researchers in the United Kingdom reanalyzed outbreaks of respiratory illness in foxhounds that had occurred in 2002 and 2003 and found evidence indicating that two distinct strains of equine influenza were the causative agents. Yet, in contrast to the apparent maintenance of the virus in the canine population in the United States, both equine-to-canine transmission events in the United Kingdom appear to have been self-limiting.

EPIDEMIOLOGY AND DISEASE TRANSMISSION

Canine influenza virus infection has as of now been documented in the United States in at least 26 states and the District of Columbia. Because this disease has recently emerged in the dog population, there is little natural immunity to influenza virus infection; and all dogs are potentially susceptible, regardless of age, breed, sex, or vaccination status. Disease is most likely to occur in dogs that are housed in groups (e.g., in shelters, boarding or breeding kennels, canine day-care centers, or veterinary clinics). When canine influenza virus is introduced to a group of susceptible dogs, infection spreads rapidly, usually resulting in a significant outbreak of respiratory disease. These outbreaks are characterized by disease in all ages of dogs, regardless of vaccination status, with morbidity rates as high as 80% to 90%. Mortality rates are lower and most likely to be 5% or less.

Canine influenza virus is shed in respiratory secretions and is highly contagious. Virus may be spread by direct dog-to-dog contact or by airborne transmission through droplets or aerosols generated by coughing or sneezing. It is likely that airborne spread of virus can occur over several feet, and the virus may survive for up to 48 hours in the environment. Fomites also play an important role in the transmission of canine influenza virus, with spread occurring through contact with infected bedding, feeding, or grooming equipment and even the clothing of personnel working with infected dogs.

The time from exposure to canine influenza virus to onset of clinical signs is approximately 2 to 4 days. Viral shedding begins as soon as 2 days after exposure, peaks at 2 to 4 days, and may persist for 7 to 10 days. Thus dogs with canine influenza may shed virus before the development of clinical signs or very early in the course of disease. This has significant implications for both diagnosis and disease control. It is also important to note that infected dogs are unlikely to be shedding virus by 10 to 14 days after infection.

There is no true carrier state for canine influenza virus infection; however, as many as 10% to 20% of infected dogs may shed virus with no apparent clinical signs. Therefore dogs that have been in contact with influenza suspects should also be regarded as potentially infectious to other dogs for 10 to 14 days after possible exposure.

CLINICAL SIGNS AND DIFFERENTIAL DIAGNOSIS

The most common clinical sign of canine influenza virus infection is a cough. The cough is typically soft and moist but may be harsh or dry. It may persist for several days or even weeks. Affected dogs may also have a serous or purulent nasal discharge. Fever may be noted in the early stages of infection and is usually transient. The signs of canine influenza virus infection are clinically indistinguishable from those of infection with other respiratory pathogens such as *Bordetella bronchiseptica*, adenovirus, or parainfluenza virus (See Chapter 147). However, when compared to kennel cough or more classic canine infectious tracheobronchitis, an outbreak of canine influenza typically

involves a much larger percentage of susceptible dogs, and disease is seen in animals that have been vaccinated against other respiratory pathogens. It is also important to remember that coinfections may occur with canine influenza virus and other kennel cough organisms.

A small percentage of dogs exposed to canine influenza virus develop a more severe form of disease characterized by persistent fever, lethargy, dyspnea, and signs of bronchopneumonia. This form of the disease may be fatal; however, it is much less common than the milder form of disease and probably accounts for fewer than 10% of cases. The initial report of influenza virus infection in racing greyhounds described a peracute hemorrhagic pneumonia with a case fatality rate of 36%. Fortunately it appears that this is an uncommon manifestation of the disease in other dog populations.

DIAGNOSIS

The laboratory diagnosis of canine influenza is based on the culture of the etiologic agent (virus isolation), the demonstration of the viral nucleic acid (polymerase chain reaction [PCR]-based assays) or viral antigen in nasal or pharyngeal swab samples (e.g., detection of antigen by immunofluorescence, enzyme-linked immunosorbent assay [ELISA], or immunoperoxidase), or the detection of virus-specific antibodies (serology). Each of these methods has both merits and disadvantages; therefore it may be necessary to combine several diagnostic tools to identify canine influenza virus accurately and rapidly. Moreover, the timing of sample collection relative to the onset of clinical signs is critical in regard to appropriate test selection. For instance, virus shedding in nasal secretions is heaviest within the first few days after infection. Therefore nasal or pharyngeal swab samples submitted for virus isolation, nucleic acid, or antigen detection should be collected early in the course of disease (i.e., within the first 24 to 48 hours after onset of clinical signs). In contrast, since insufficient time has passed to allow for production of a detectable antibody response, serologic testing often may produce a negative result in the first few days after infection.

Virus Isolation

Although virus isolation from clinical samples is critical for epidemiologic investigation and for future vaccine production, this technique may have limited value for diagnostic purposes. Virus isolation can take a minimum of 2 to 3 days; and the success of this technique for detection of infectious virus is influenced by virus strain, amount of viable virus present in the sample, and sample collection and storage techniques. Moreover, if the amount of virus shed is low, several serial passages may be required before sufficiently high viral titers are reached to allow detection using conventional hemagglutination assays. For sample collection, a short polyester-tipped swab should be used for the collection of secretions on the nasal mucosa. Cotton-tipped swabs should be avoided since influenza virus has been found to adhere to the cotton fibers, thus decreasing the chances of virus recovery. Optimally the swab should be placed in sterile

viral transport medium (often available from a diagnostic laboratory) and kept on ice or refrigerated until further analysis.

Antigen Detection

The most important advantages of diagnostic tests aimed at the detection of viral antigen over traditional virus isolation are the faster turnaround time and the ability to detect virions that have lost their infectivity. Immunofluorescence uses influenza-specific fluorochrome-labeled antibodies to detect virus-infected cells. The technique is highly sensitive and can be used to detect viral antigen in a broad range of clinical samples such as frozen tissue sections, tissue imprints, cells obtained from nasal scrapings, tracheal washes, and bronchoalveolar lavage fluid. Commercially available antigen-capture ELISA assays originally were developed for the rapid, on-site detection of human influenza A viruses (e.g., Flu OIA assay, Biostar; Directigen Flu-A assay, Becton Dickinson Microbiology Systems). The tests have been designed to detect the human influenza A virus nucleoprotein. Because the viral nucleoprotein is highly conserved among influenza A viruses of different subtypes and lineages, these assays have also been used to detect influenza infection in other species. For example, these rapid stall-side tests have been evaluated for the detection of influenza virus in horses and have been found to perform with high specificity and reasonable sensitivity. Similarly, recent studies conducted in dogs suggest that the commercial ELISA-based tests perform with a sensitivity similar to that of traditional virus isolation.

Polymerase-Chain Reaction–Based Assays

Several diagnostic laboratories offer PCR-based tests (conventional and/or real-time PCR) for the diagnosis of canine influenza virus infection. PCR-based assays are extremely sensitive and theoretically can detect a single copy of the target nucleic acid in a sample. However, because of the high sensitivity of the assay, the greatest challenge facing the diagnostic application of PCR is the production of false-positive results. Nonetheless, PCR-based testing offers a more sensitive tool for the diagnosis of canine influenza than conventional techniques such as virus isolation or immunoassays. Real-time PCR assays are being used with increasing frequency in veterinary diagnostic laboratories. In contrast to conventional PCR methods, real-time PCR does not require post-PCR processing steps (e.g., gel electrophoresis and determination of fragment size) and therefore can generate results within 4 to 5 hours. By using a target-specific fluorescent probe, real-time PCR can also be used for quantification of virus and can be and has been used in routine diagnostic settings.

Antibody Detection

Detection of virus-specific antibodies has been and continues to be an important tool in the diagnosis of canine influenza. Because most serologic assays are relatively easy to perform and cost-effective and large numbers of samples can be tested simultaneously, serologic testing is

particularly useful in large-scale population surveillance. However, although it is useful, there are several limitations to serologic testing. Although the presence of antibody indicates exposure to antigen, it does not necessarily signify active infection or disease. Furthermore, antibody is not always detected in the presence of active infection. Experimental data obtained from dogs infected with canine influenza virus indicate that measurable antibody titers typically develop 7 or more days after infection. Therefore antibody may not be present during the first week of active infection, which is the period that is often most critical for disease management in settings where large numbers of dogs are housed together.

THERAPY

In the majority of affected dogs canine influenza is a self-limiting respiratory disease that does not require medical therapy. Secondary bacterial infections may complicate canine influenza and may manifest as purulent nasal discharge, persistent fever, or signs of pneumonia. These complications should be managed with antibiotic therapy. For dogs with bronchopneumonia, ideally antibiotic choices should be based on the results of culture and antibiotic sensitivity testing of samples obtained by transoral or transtracheal washes or bronchoalveolar lavage. If culture and sensitivity testing cannot be performed, broad-spectrum antibiotics that achieve adequate concentrations in the respiratory tract should be selected. Depending on the severity of the disease, dogs with pneumonia may also benefit from intravenous fluid therapy, nutritional support, oxygen therapy, nebulization, and coupage (Chapter 149).

Antiviral drugs such as oseltamivir (Tamiflu, Roche) are not recommended in the management of canine influenza. The dose, duration, safety, and efficacy of this therapy are all currently unknown in dogs. In addition, these medications should be reserved as a vital defense for the protection of human health.

DISEASE CONTROL

Canine influenza should be considered in the differential diagnosis of any dog with acute cough, fever, or nasal discharge. This is particularly important if the dog has a recent history of exposure to other dogs such as at a canine day-care center, shelter, or boarding facility. Dogs that are considered to be influenza suspects should be separated from other dogs when presented to a veterinary clinic. Veterinary staff should wear a disposable gown, gloves, and shoe covers when working with influenza suspects; examination room surfaces and tables and any in-contact equipment should be disinfected when the patient leaves the hospital. If an influenza suspect requires hospitalization (e.g., for the management of pneumonia), the patient should be placed in an isolation facility to reduce the risk of disease transmission to other hospitalized patients. Again, disposable protective clothing should be worn when handling the patient, and care must be taken to avoid spread of virus by fomites. When determining the need for isolation of influenza suspects, it should be remembered that shedding of infectious virus

ceases by 10 to 14 days after infection and that exposed dogs may shed virus before the onset of clinical signs.

If a dedicated isolation facility is not available in the veterinary hospital, strict barrier nursing precautions must be used in the management of hospitalized influenza suspects. These precautions include the use of dedicated or disposable protective clothing when working with the patient; maximum physical separation from other dogs in the same room; disinfection of all in-contact items such as food and water bowls, medical equipment, and bedding; the use of disinfectant foot baths or foot mats; and rigorous hand washing between patients. If staffing levels allow, personnel caring for influenza suspects should avoid contact with other hospitalized patients.

When influenza outbreaks occur in groups of dogs, it is important to separate exposed or infected dogs from unexposed dogs. Because the infection spreads rapidly and virus shedding can precede the onset of clinical signs, all dogs present in a facility should be considered infected at the time of diagnosis. These animals should subsequently have no direct or indirect contact with unexposed dogs for 14 days. In addition to physical separation of exposed or infected dogs from unexposed susceptible dogs, it is important to avoid transmission by fomites such as clothing and equipment used by animal care personnel. If possible, exposed or infected dogs and unexposed susceptible dogs should be maintained in areas with separate air supplies and managed by separate teams of staff. However, these measures may not be possible in all facilities.

Canine influenza virus is inactivated by many detergents and disinfectants. Hand washing with soap between patients reduces the spread of infection, and surfaces should be decontaminated by cleaning followed by disinfection. Cleaning is necessary to remove organic debris that may inhibit or inactivate disinfectants. Bleach, alcohol, quaternary ammonium compounds, and oxidizing agents are all effective for the inactivation of canine influenza virus.

PREVENTION

Although a number of manufacturers are in the process of developing vaccines, at this time there are no licensed canine influenza vaccines on the market. Therefore the two main principles used in controlling canine influenza infection and disease are the reduction in the spread of virus between dogs and the prevention of secondary complications. Under optimal circumstances dogs should be isolated for up to 4 weeks before introduction into a disease-free population. During this isolation period no clinical signs should be detected, and no new

animals should be introduced into the isolation facility. Since these criteria may be too stringent for most animal facilities such as humane shelters and boarding kennels, 2 weeks of full isolation may constitute an acceptable compromise. Other management procedures such as segregating dogs in separate rooms can be valuable since segregation may allow for containment of disease outbreaks. As outlined previously, sharing of feeding, grooming, and cleaning equipment also increases the risk of disease spread.

PUBLIC HEALTH CONSIDERATIONS

As discussed in the introduction, influenza A viruses occasionally are transmitted directly from one host species to another. Yet in many instances these transmission events are self-limiting, and the introduced viruses are only rarely maintained in the new host species. Moreover, a number of influenza virus lineages are rarely detected in animals other than their typical host. For example, although the susceptibility of human volunteers to infection with H3 equine-lineage viruses has been demonstrated, there is no evidence that horse-to-human or human-to-horse transmission routinely occurs under natural conditions. Similarly, there is no evidence at this time that canine-to-human transmission of influenza takes place. However, given the plasticity of the influenza virus genome, it is possible that at some time in the future the canine viruses may acquire the capability to infect another host species. This emphasizes the central role of the veterinarian in the control of canine influenza because only by continuing to sample animals with influenza-like illness and submitting these samples for virus isolation, antigenic, and genetic analyses will veterinarians be able to assess the extent of genetic evolution and to gauge the risks posed to other species by the canine H3N8 viruses.

Feline Infectious Peritonitis: Therapy and Prevention

DIANE D. ADDIE, *Etchebar, France*
TAKUO ISHIDA, *Tokyo, Japan*

Feline infectious peritonitis (FIP) has been considered an incurable disease, and a diagnosis of FIP usually resulted in euthanasia. Recent advances in the understanding of FIP pathogenesis and novel diagnostic tests now enable earlier and more accurate diagnosis of FIP. With the recent introduction of recombinant *feline* interferon ω (rFeIFN- ω), there is hope for an effective treatment regimen in some cases.

The first step in FIP treatment is establishing an accurate diagnosis. Despite many manufacturers' claims that their tests are FIP tests, currently there is no specific FIP test. Existing tests actually detect feline coronavirus (FCoV) antibodies or viral RNA. Only histopathology can diagnose FIP unequivocally. This is because the majority of cats that become infected with feline coronavirus (FCoV) do *not* develop FIP (Fig. 285-1); therefore *no healthy FCoV-infected cat should ever be said to have FIP*. The problem for clinicians is distinguishing look-alike conditions from FIP in the FCoV-infected cat. Details of how to do this and further information can be found on catvirus.com or other literature sources.

PATHOGENESIS

Cats become infected with FCoV orally, usually indirectly, by contact with FCoV-contaminated cat litter. FCoV is highly infectious, and in a multicat household over 90% of cats will seroconvert. Virus is shed in the feces from 2 days after infection, and cats seroconvert 18 to 21 days after infection. Initial infection may be clinically inapparent or accompanied by transient upper respiratory tract signs or diarrhea, which may be mild but can occasionally be extremely severe. Most cats clear the virus after 2 to 3 months of fecal shedding, although some cats are persistently infected. The mechanism for viral clearance is not wholly understood. Chronic carrier cats are usually healthy, although one of the authors (DA) has observed some cats develop chronic large intestinal diarrhea in older age.

FCoV antibody titers in infected cats that do not develop FIP tend to decrease to zero over time (Addie and Jarrett, 2001). Increasing FCoV antibody titer in a healthy cat usually is followed by a decrease to zero over several months (Addie and Jarrett, 2001). However, in the experience of one of the authors (TI), if accompanied by polyclonal gammopathy and rising α_1 -acid glycoprotein (AGP) levels, rising antibody titers occasionally may be associated with FIP.

FIP is a misnomer since many cats do not present with peritonitis. The histopathologic lesion of FIP is a phlebitis or perivascular pyogranuloma. Recent developments in understanding the pathogenesis of FIP are useful in understanding how clinical signs develop and for devising new strategies for therapy. Using immunohistochemistry FCoV has been found within monocytes adhering to blood vessel walls and extravasating to adjacent tissues (Kipar et al., 2005). This is a key event in the development of FIP since FCoV-infected macrophages release a number of cytokines that drive the clinical disease. Interleukin-6 (IL-6) stimulates B lymphocytes to differentiate into plasma cells, and high IL-6 levels found in cats with FIP are the likely cause of hypergammaglobulinemia. In early infection IL-6 stimulates hepatocytes to release acute-phase proteins, including AGP and high AGP levels can be used to aid in the diagnosis of FIP. A rise in AGP levels was found not only in cats that develop FIP but also transiently in cats in contact with a sick FIP cat (Giordano et al., 2004), leading to speculation that the early AGP response could, in fact, be protective against FIP development (Addie, 2004).

Why one cat develops FIP while other infected in-contact cats remain healthy is unknown. Some laboratory strains are exceptionally virulent, causing FIP in almost every cat infected with them; these have been called *FIPVs*. There are also biotypes with far less virulence, commonly called *feline enteric coronaviruses* (*FECVs*). These laboratory strains have varying ability to replicate in monocytes, and it has been assumed that the occurrence of FIP was related solely to the virulence of the strain of virus infecting the cat. However, a recent study has shown that monocytes of different cats support FCoV replication to varying extents (Dewerchin, Cornelissen, and Nauwynck, 2005) and that some cat's monocytes do not support viral replication at all, which could be an explanation for the occurrence of FCoV-resistant cats previously reported by Addie and Jarrett (2001). The "internal mutation theory" (i.e., that FECVs must mutate to FIPVs for FIP to arise) has been questioned after sequence analysis of the entire genome of viruses found both in the gut and systemically in a cat that died of FIP were found to be identical (Dye and Siddell, 2007). The recent advent of quantitative (or real-time) polymerase chain reaction will enable the role of viral load in FIP development to be investigated more fully.

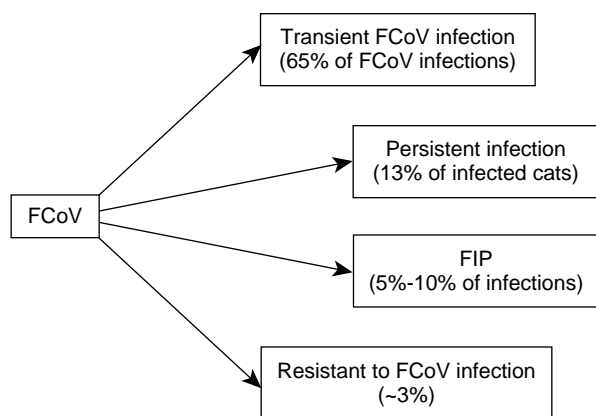

Fig. 285-1 Potential outcomes of feline coronavirus infection. (The percentages are approximate and do not add up to 100% because not all of the cats in the study had sufficient samples taken for their status to be defined [Addie and Jarrett, 2001]).

THERAPY

Current Therapies

Clinical FIP is caused by the cat's inflammatory and immune-mediated response to FCoV. Therapy is aimed at suppressing that inflammatory and immune-mediated response, usually with corticosteroids. One problem with corticosteroid therapy is that it suppresses the immune response nonselectively, suppressing both cell-mediated and humoral immune responses. It is likely that one would wish to support cell-mediated responses while suppressing humoral responses, at least in effusive FIP. It is possible that in noneffusive FIP both cell-mediated and humoral responses should be suppressed.

Until recently FIP was almost 100% fatal. However, two publications have reported cure or remission in some cats.

Administration of a thromboxane synthetase inhibitor with prednisolone reportedly cured one cat and gave remission for 8 months in a second effusive FIP (Watari et al., 1998). However, one of the authors (TI) has been unable to reproduce this result. Use of rFeIFN- ω (Virbagen- ω , Virbac) and prednisolone resulted in recovery in 4 of 12 cats and remission of 4 and 5 months in two others (Ishida et al., 2004). However, a second study evaluating rFeIFN- ω therapy was unable to show an effect on survival time or quality of life in cats with FIP (Ritz, Egberink and Hartman, 2007).

IFN- ω is a monomeric glycoprotein distantly related in structure to IFN- α and IFN- β but unrelated to IFN- γ . It has antiviral properties, stimulates natural killer cell activity, and enhances expression of major histocompatibility complex class I (but not class II) antigens. Although effusive and noneffusive FIP are not distinct diseases but rather gradations of the same process.

The use of interferons for the treatment of cats infected with FIP is controversial, though the authors believe such therapy is warranted considering the relative lack of therapeutic options. Both negative treatment studies (Ritz, Egberink, and Hartmann, 2007) and positive treatment studies (Ishida et al., 2004) have been published. Our treatment approach to the cat with an effusive or noneffusive form of FIP infection is outlined in Box 285-1. Only over time and with additional studies will the effectiveness of rFeIFN- ω or other therapies in the treatment of FIP become evident.

Possible Future Therapies

A number of other drugs also have theoretic application in the treatment of cats with FIP and are offered in Table 285-1. Most have never been used to treat FIP or have been used in only a few cats; thus the reader should exercise appropriate caution when choosing patients to receive these unproven drugs.

Box 285-1

Treatment Protocols Used for Effusive and Noneffusive Feline Infectious Peritonitis

EFFUSIVE

Glucocorticoids

Dexamethasone 1 mg/kg intrathoracic, intraperitoneal or intravenous once followed by:

- Prednisolone sliding dose; 4 mg/kg q24h for 10-14 days, reducing to 2 mg/kg q24h for 10-14 days, then 1 mg/kg q24h for 10-14 days, then 0.5 mg/kg q24h for 10-14 days, then 0.25 mg/kg q24h for 10-14 days, then 0.25 mg/kg q48h and so on, ceasing after complete remission of clinical signs; if, at any point, the cat's condition regresses, go back to the previous dose

Feline interferon- ω

1 million units(MU)/kg subcutaneously q48h, reducing to once weekly if remission occurs

Broad-spectrum antibiotics

NONEFFUSIVE

Glucocorticoids

Prednisolone sliding dose as for effusive feline infectious peritonitis (FIP); with FIP-related uveitis topical corticosteroids should be used.

Feline interferon- ω

50,000 units per cat PO q24h until acid glycoproteins, serum amyloid A, globulins, hematocrit, lymphocyte count, and clinical signs return to normal.

Diluting feline interferon- ω

Feline interferon (IFN)- ω (Virbagen Omega, Virbac) comes in vials of 10 MU. It is reconstituted with 1 ml of diluent. Ten aliquots of 0.1 ml (1 MU per syringe) are prepared in insulin syringes. Nine syringes out of 10 are kept in the freezer (can be stored up to 6 months). The tenth syringe is diluted with 19.9 ml of sterile 0.9% saline solution to obtain 20 ml of solution containing a total of 1 MU (50,000 U/ml) of feline IFN- ω . This syringe is stored in the refrigerator at +4°C, where it will last up to 3 weeks (do not freeze diluted IFN- ω because it is unstable). Dosage: 1 ml of this diluted solution (containing 0.05 MU) orally daily, using the syringe without the needle.

Table 285-1

Potential Future Drugs for the Treatment of Feline Infectious Peritonitis*

Potential Treatment	Suggested Mode of Action	Suggested Dosage	Comments
Ozagrel hydrochloride	Thromboxane synthetase inhibitors	5-10 mg/kg twice a day	Cured one cat and gave remission for 8 months in a second effusive feline infectious peritonitis (FIP); no cures in a second study (Ishida, unpublished)
Infliximab (Remicade, Centocor)	Monoclonal antibody against tumor necrosis factor (TNF)- α	Unknown	Use in effusive and non-effusive FIP; increases risk of bacterial infections
Etanercept (Enbrel, Immunex Corp.)	Soluble p75 TNF- α receptor coupled to Fc portion of immunoglobulin G	Unknown	Use in effusive and non-effusive FIP; increases risk of bacterial infections
Dehydroepiandrosterone (DHEA)	Down-regulates endothelial adhesion molecules and reduces neutrophil extravasation		Use in effusive but not in non-effusive FIP
16 α -Bromo-epiandrosterone (epiBr)	Synthetic derivative of DHEA	40 mg/cat/day	Use in effusive but not in non-effusive FIP
Cimetidine	Stimulates cell-mediated immunity and reverses lymphopenia	50 mg once a day	Safe; may be more useful in effusive than non-effusive FIP
Thalidomide	Antiinflammatory and pushes immune response from Th2 to Th1	50-100 mg once a day in the evening	Safe but difficult to source
Salvianolic acid B	Matrix metalloproteinase 9 inhibitor	10 mg/kg once a day	Likely to be more useful in effusive than non-effusive FIP
Tropisetron	5-hydroxytryptamine (3) receptor antagonist	300 mcg/kg once a day	
Coronavirus 3C-like protease inhibitors	Anticoronavirus drug	Intravenous administration likely	Not yet available

*NOTE: Listed in Table 285-1 are potential theoretic treatments for cats with FIP that are lacking published clinical or research studies. The reader should exercise appropriate caution in use of these unproven drugs.

PREVENTION OF FELINE INFECTIOUS PERITONITIS AND FELINE CORONAVIRUS INFECTION

There is no single, easy method to prevent FIP; a combination of the techniques discussed in the following paragraphs is most effective. Obviously, if cats do not become infected with FCoV, FIP will not develop.

Prevention of Feline Infectious Peritonitis by Vaccination

The one commercially available FIP vaccine, a temperature-sensitive mutant (Primucell, Pfizer) that only replicates in the cooler nasal mucosa of cats, has been beset by controversy (also see Chapter 280). Basically there are two questions: is it effective, and does it cause antibody-dependent enhancement of disease?

In an independent study in Switzerland, cats entering a rescue cattery were vaccinated with Primucell. There was no difference in mortality rates from FIP between vaccinated and unvaccinated cats in the first 150 days after vaccination (Fehr et al., 1995, 1997). However, after 150 days there was a marked reduction in the number of cats succumbing to FIP in the vaccinated but not the control group. When the investigators returned to stored blood samples from the cats that developed FIP, they found

that these cats were already viremic at the time of vaccination (Fehr et al., 1997) (i.e., they were incubating FIP at the time of vaccination). Only FCoV-naïve cats can be prevented from developing FIP by vaccination.

From this study it is possible to suggest certain vaccine guidelines:

- All cats going into rescue and boarding catteries should be vaccinated against FIP.
- Cat breeders should maintain their kittens FCoV-free until FIP vaccination is possible (current recommendation is that vaccination commences at 16 weeks of age).

Another point sometimes made in relation to the efficacy of Primucell vaccine is that it is derived from a type II FCoV, the strain DF2. There are two types of FCoV: type I, which is wholly feline; and type II, which is a recombinant virus with much of the viral spike protein being derived from canine coronavirus. The majority of field strains of FCoV are type I. In the study mentioned previously, it is likely that most of the FCOVs the cats naturally encountered in the rescue shelter were type I since a recent study showed that type I is the most prevalent type in Switzerland (Kummrow et al., 2005). Thus, although unproven, the vaccine is likely to be equally effective against types I and II FCoV.

Antibody-dependent enhanced (ADE) FIP is a phenomenon in which vaccination contributes to disease pathogenesis. ADE FIP is the reason why most experimental FIP vaccines have failed (i.e., more vaccinated cats than unvaccinated cats developed FIP, and they did so more quickly and with worse clinical and pathologic features than unvaccinated cats). In two laboratory experiments in which Primucell appeared to cause ADE, a highly virulent laboratory strain of FCoV was used in the challenge (McArdle et al., 1995; Scott, Olsen, and Corapi, 1995). In contrast, in two field trials with Primucell the vaccine was protective (Fehr et al., 1995, 1997; Postorino-Reeves, 1995). One recommendation of the Second International Feline Coronavirus and Feline Infectious Peritonitis Symposium workshop was that the 79–1146 strain of FCoV not be used in vaccine challenge experiments since it is too virulent to give an accurate representation of how the vaccine would perform in field conditions (Addie et al., 2004).

Prevention of Feline Coronavirus Infection and Feline Infectious Peritonitis by Hygiene and Quarantine

FIP vaccination is not 100% protective; thus it is preferable that cats never be exposed to FCoV infection. This is especially true for cat breeders and their kittens since kittens cannot be vaccinated before 16 weeks of age but they are susceptible to infection after 5 to 6 weeks of age. Indeed, in large catteries virus load may even overcome maternally derived antibody to cause infection in kittens as young as 2 weeks (Addie et al., 2004).

FCoV is shed mainly in feces; therefore avoiding FCoV infection centers around litter tray hygiene and limiting contact of FCoV-naïve cats with FCoV-contaminated cat litter or fomites. FCoV is killed by many disinfectants, including household bleach. Regular disinfection of litter trays helps to minimize environmental viral load. Provision of adequate numbers of litter trays in multicat households helps ensure that cats do not have to use a soiled tray, and self-cleaning litter trays or nontracking cat litter should be used wherever possible. Regular vacuum cleaning reduces environmental contamination by microscopic particles of infected cat litter.

FCoV infection is maintained in a household or cattery by continual cycles of infection and reinfection (Foley et al., 1997, Addie et al., 2003). Commonly available reverse transcriptase polymerase chain reaction tests can detect FCoV in feces, so that it is possible to establish which cats are shedding FCoV and separate them from cats that are not shedding FCoV. Virus shedding usually continues for 2 to 3 months, although it can be longer. Cats that shed FCoV for 9 months or more are likely to be lifelong carriers of the virus (although one cat stopped shedding virus after 5 years). By repeat testing and separation of shedding from nonshedding cats, it is possible to eliminate FCoV from a multicat pet or breeding household. Quarantine and testing of new-arrival cats prevents FCoV from being (re)introduced into such a household.

Kittens are protected from FCoV infection by maternally derived antibodies until they are between 5 and

6 weeks of age. Thus it is possible to prevent FCoV infection of young kittens by isolating them with their queens from birth onward and removing them to a clean environment when they are 5 to 6 weeks old. For this technique to work, the breeder requires a thorough understanding of barrier nursing techniques. Transplacental transmission of FCoV does not appear to occur.

Many cats with FIP have a history of having recently been stressed (e.g., by a neutering operation). Cats at risk for FIP are easy to identify: they are purebred or have a history of having come from a multicat environment such as a rescue shelter or pet shop. Fifty percent of FIP occurs in cats under 2 years old. It is possible that the development of FIP in these cats could be averted by determining whether or not they are infected (e.g., by testing their feces for FCoV) and delaying elective surgery until the cat has cleared the virus. Cats are at greatest risk of developing FIP soonest after FCoV infection (Addie et al., 1995), and the risk diminishes with time. When there is no choice but to go ahead with surgery, stress can be minimized as much as possible (e.g., by not keeping the cat in a waiting room with dogs). For the reasons outlined previously, it would be prudent to advise clients to avoid stresses such as visits to the boarding cattery until FCoV-infected cats have cleared the virus.

In summary, FIP therapy is still in early stages and likely can only be advanced after a definitive diagnostic test is developed. Therefore all efforts should be directed to preventing FIP by careful cat management (good hygiene, stress reduction, quarantine) and by vaccination.

CHAPTER 286

Control of Viral Diseases in Catteries

DIANE D. ADDIE, *Etchebar, France*

The control of viral disease in catteries will depend largely on the type of cattery. Catteries mainly fall into six distinct types with different feline populations:

1. **Boarding/Quarantine:** Transient population, but mainly vaccinated. Indoor for duration of cattery stay, but possibly free-ranging before then.
2. **Rescue:** Transient population of unknown vaccine status. Indoor for duration of cattery stay, but a mix of free-ranging and indoor housing prior to relinquishment.
3. **Breeding:** Longer term population, closed, but with possible contact with other cats for mating, or at shows. Vaccination and infectious disease screening variable. Usually indoor housing.
4. **Multicat pet household:** Longer term population, free-ranging or indoor housing. Vaccination and infectious disease screening variable.
5. **Veterinary premises:** Transient population of known and unknown infectious disease status.
6. **Specific pathogen free (SPF):** Closed, indoor population with strictly known vaccination and infectious disease status.

Clearly, the problems encountered within each of the different types of cattery are extremely diverse. In this chapter I will approach the control of the main feline viral diseases, referring only to cattery type when it affects the control of that particular virus. The infections considered in this chapter are listed in Table 286-1. Information on more unusual viral infections, such as Borna virus and Aujeszky's (pseudorabies), are considered in other textbooks (Greene, 2006). Full clinical details, treatment, and diagnosis of viral diseases are omitted in this chapter, except where they affect disease control (for more therapy details, see Section XIII in this volume). The most

Table 286-1

Viral Transmission and Shedding

Infection	Survival Outside Host	Virus Shedding	Quarantine Time Before Testing	Mode of Transmission	Prevention of Infection
FCV	Days to weeks	Continuous, half-life 75 days	7 days	Direct contact, sneezed droplets	Test all cats before mixing them; excellent hygiene; sneeze barriers
FHV	12-18 hours	Intermittent, lasts 7-14 days	3 weeks	Direct contact, sneezed droplets	Vaccination prevents clinical signs, but not infection; testing reliable if positive result, but since latent infection, negative result not definite
FeLV	Minutes	Continuous	12 weeks	Direct contact essential, transplacental	Test all cats before mixing them; vaccination
FIV	Minutes	Continuous*	12 weeks	Direct contact essential—mainly biting; transplacental rare	Test all cats before mixing them
FCoV/FIP	Up to 7 weeks	Usually continuous	3 weeks (antibody, 1 wk virus)	Indirect, through cat litter/shared litter trays, poop scoops; not transplacental	Test all cats before mixing them; excellent hygiene
Parvovirus	Up to a year	Usually only 24-48 hours, but can be up to 6 weeks	None	Indirect, transplacental	Vaccination; excellent hygiene and disinfection; don't have too many unvaccinated cats/kittens on premises
Feline pox virus		Not infectious to other cats	None	Contact with small rodents	Can't stop cats hunting!
Rabies	Minutes	Continuous	None if adequate antibodies: >0.5 units or 6 months	Biting	Vaccination is effective

FCV, Feline calicivirus; FCoV, feline coronavirus; FeLV, feline leukemia virus; FHV, feline herpesvirus; FIV, feline immunodeficiency virus; FIP, feline infectious peritonitis.

*Virus load is very low during the long asymptomatic phase.

essential part of infectious disease control in all types of cattery, and for all infectious diseases, is good hygiene, so we will begin with that.

CONTROL OF VIRAL TRANSMISSION BY HYGIENE

The essence of “barrier nursing” is preventing transfer of infection within the cattery. Clean cats/food bowls/litter trays/pens should be dealt with before dirty ones. The cats' food should be distributed before dealing with litter trays or cleaning kennels; ideally there would be different people dealing with the food and the cleaning. Clean litter trays should be put out in the runs first, and then the dirty trays should be picked up; a clean tray should never be touched after a dirty one, and the same poop scoop or litter rake should never be used from one pen to another! The first rule is to deal first with the least-infected area of the surgery or cattery (for example, any kittens or surgery cases), and gradually move up to the most-infected area (locations where there are animals sick with infectious disease or known healthy carriers of infection). It is useful to establish a routine order of tending to the animals in a cattery so that the least-infected

area is always dealt with first. This applies to cleaning of litter trays, feeding, grooming, or even when the cats are petted.

Indirect transmission of viruses can occur on hands, shoes, or clothes when moving about the cattery. Therefore hands should be washed or disinfected before every contact with a cat or kennel. Ideally there should be disinfectant foot baths between each major area of a cattery.

Kittens should have food bowls, litter trays, and litter scoops that are used only for them, and these should be cleaned daily and disinfected/steam cleaned once or twice a week. The beds, dishes, litter trays, and scoops of cats in different areas of the cattery should be color coded so that it is immediately obvious if something is in the wrong place. Thus if a kitten's litter tray had been inadvertently put into the pen of an adult cat, it could be spotted instantly, removed, and disinfected before being returned to the kittens' area.

Cattery design is crucial. Sneeze barriers are essential for the control of airborne viruses in all cattery categories except for the pet household. It is vital that air conditioning pushes the air past the cat straight to the outdoors (i.e., positive pressure rather than negative pressure) or to a virus filter system and not past other cats.

Quarantine is useful to establish whether new cats are incubating disease. For example, feline herpesvirus (FHV) shedding recrudesces following stress, and the biggest stress a cat can face is being rehomed or going to a boarding cattery; thus virus is shed again, with or without accompanying upper respiratory tract signs. The United Kingdom quarantines cats from countries with endemic rabies for up to 6 months to allow them time to display clinical signs of rabies if they were infected. The time required for quarantine depends on which pathogen is the concern (see Table 286-1).

FELINE CALICIVIRUS

Feline calicivirus (FCV) is a ribonucleic acid (RNA) virus. It exists in cats as a quasispecies, continually mutating to evade the neutralizing antibodies of its host (Radford et al., 1998). Vaccination ameliorates clinical signs but doesn't prevent virus shedding and may even promote carrier status. Indeed, 40% of so-called vaccine breakdowns are caused by the vaccinal strain. If a live vaccine is aerosolized or inadvertently spilled onto the cat and the cat licks it off, it can infect the cat; thus catteries that are free of FCV preferably should use killed, or antigen-only, vaccines.

Natural selection has driven field strains of FCV away from older vaccine strains. In cattery situations vaccines containing newer FCV strains should be used to give as broad a protection as possible. FCV strains causing virulent systemic disease (VSD) (Pesavento et al., 2004; Coyne et al., 2006) tend to arise *de novo* in the cattery situation; therefore there is no benefit in vaccines containing a FCV VSD strain. For situations in which rapid onset of protection is needed, intranasal vaccines should be considered (Radford et al., 2007).

Vaccination alone will not prevent FCV spread in a cattery. SPF and breeding catteries can avoid its introduction completely by testing new cats prior to introduction, provided the test is sensitive enough (virus isolation of an oropharyngeal swab). Reverse transcriptase–polymerase chain reaction [RT-PCR] has to be used with caution because of the high variability of the FCV genome; some tests will give false negative results. Fortunately FCV is shed continuously (as opposed to intermittently).

FCV is shed by 10% of pet cats, 25% of cats at shows, 40% of colony cats, and almost 100% of cats with chronic lymphocytic plasmacytic gingivostomatitis. The half-life of FCV shedding is 75 days; thus there should be 2.5 months between tests of cats to detect when they have stopped shedding FCV.

Cat breeders preferably should use only FCV-negative queens. If this is not possible, maternally derived antibody (MDA) lasts up to 2 to 3 weeks; thus kittens can be weaned early and kept in isolation from infected individuals.

At time of writing, no antiviral drug is effective against FCV.

FELINE HERPESVIRUS

FHV-1 is a deoxyribonucleic acid (DNA) virus, and there is essentially only one serotype (reports of a FHV-2 were never fully scientifically confirmed). Viral persistence in the host cat is completely different from the other flu

virus, FCV, in that FHV becomes latent within the trigeminal ganglion of the host. The trigeminal ganglion is an immune-privileged site, and the DNA of the FHV exists in the ganglion without expressing viral proteins. However, if the cat is stressed (e.g., because of rehoming or pregnancy), the virus can re-emerge, travel down the trigeminal nerve, and be shed in the oropharynx and/or the eye. Recrudescence of FHV shedding occurs 7 to 10 days after stress and lasts for 1 to 2 weeks. Vaccination prevents the worst of clinical signs, but does not prevent infection of the cat or the development of latency. It is estimated that 90% of cats have been exposed to FHV and 80% of exposed cats become latently infected for life. Testing for infection is of limited value because negative results may simply mean that the virus was latent at the time of testing.

As with FCV, prevention of FHV depends on factors such as good hygiene. However, the amino acid l-lysine competes with arginine in the formation of the herpesvirus particle, and a dosage of 250 to 500 mg/cat/day may reduce FHV shedding. Breeders attempting to reduce FHV infection of the neonate may stress the queen 3 to 4 weeks before kitting by moving her to a room or chalet on her own so that FHV shedding will have passed by the time the kittens are born. MDA is only protective for up to 2 to 3 weeks; thus the kittens should be weaned early and then kept in total isolation from the adult cats in the household.

Aside from topical preparations for ocular FHV, use of human antiherpesvirus drugs in cats is limited by their poor efficacy against FHV and by their toxicity in the cat (Maggs, 2001).

FELINE LEUKEMIA VIRUS

Feline leukemia virus (FeLV) is an RNA retrovirus. For an RNA virus it is remarkably conserved. The virus has avoided the need to mutate to evade the cat's immune response by switching off the cat's immune response, which is why it causes immunodeficiency. FeLV is a fragile virus, requiring direct contact for transmission. Transplacental transmission occurs.

Infection to viremia takes 3 to 6 weeks, which is why it is important to retest a negative cat suspected of FeLV exposure after 6 to 12 weeks. Following oronasal exposure, FeLV infects local lymph nodes and travels to bone marrow and other lymphoid tissues. It then moves to mucosa, where it is shed mainly in the saliva (although possibly in the tears, urine, feces, and milk as well). The cat has the opportunity to recover at any of these stages of infection, so it is important to retest a healthy cat with a positive FeLV test after an interval of 12 weeks.

After the age of 4 months cats are increasingly able to mount an effective immune response to FeLV. However, this age-related resistance to FeLV can be overwhelmed by high viral doses such as are found in infected multi-cat households in which approximately 40% of cats can be viremic. Cytotoxic T cells appear early in FeLV infection (in a week). Immunity to natural FeLV exposure can be measured by detecting virus-neutralizing antibodies (VNAs), which appear from 6 weeks after infection.

Cats with active FeLV infection have a VNA titer of 0. The immune response to vaccines is not easy to measure commercially.

No FeLV vaccine is 100% effective. Vaccination has a place in free-roaming pet cats but should not be necessary for veterinary surgeries or boarding or rescue catteries (since cats from different backgrounds should not be allowed to mix and FeLV is unlikely to be transmitted indirectly). Neither should breeding or SPF catteries require vaccination, since these cats are usually kept indoors and should have been tested and found to be FeLV negative before being introduced into these catteries.

It is important to use in-house diagnostic tests for FeLV wisely (Table 286-2). Point of care FeLV tests for FeLV p27 antigen should be considered as screening tests; accordingly, a positive result should be confirmed by a more specific test, such as immunofluorescence (IF), virus isolation (VI), or polymerase chain reaction (PCR), which will usually be carried out by a specialist or reference laboratory. The reason for confirmation is that in situations in which the prevalence of FeLV infection is very low, as is the case in many populations of healthy cats, the positive predictive value of an in-house test is relatively low (i.e., the occurrence of false positive results is relatively high). Cats that are persistently viremic will test positive with all of these diagnostic tests. The advantage of immunofluorescence and virus isolation tests is that they definitively detect viremic, virus-excreting cats and can be considered the gold standard for FeLV diagnosis. PCR is very sensitive and detects proviral DNA in leukocytes. However, many, if not all, cats that recover from FeLV infection and lead perfectly healthy lives without excreting virus will also be positive on PCR testing. Quantitative, real time PCR avoids some of this problem in that high virus load is associated with viremia, but it cannot discriminate completely between viremic and nonviremic cats.

FELINE IMMUNODEFICIENCY VIRUS

Feline immunodeficiency virus (FIV) is a fragile RNA retrovirus, easily killed by disinfectants. FIV usually is not transmitted indirectly, except by reusing syringes or operating kits or using dental descalers from cat to cat without sufficient hygiene. It is transmitted mainly by biting and occasionally by sharing food bowls or mutual grooming. It is rarely transmitted transplacentally or in the milk, but it is possible that an FIV-positive queen could infect her kittens when she bites through the umbilical cord or when she grooms them.

Most FIV tests detect antibody, not virus (the major exception being PCR, which detects viral DNA as provirus in the cat's genome). The period from infection to seroconversion takes up to 12 weeks; therefore antibody testing should be 12 weeks after suspected exposure. In-house FIV antibody tests can give false-positive results; thus they should be confirmed by gold standard tests (immunofluorescence, western blotting) (see Table 286-2). In addition, some FIV-infected cats don't have detectable antibody; thus a viral detection test such as PCR of the buffy coat should be used.

Transmission of FIV should not be an issue in most catteries, provided that cats from different backgrounds aren't mixed. The main situation in which FIV is a problem is the multicat pet household (cats can be screened before introduction, but if they are free ranging, they may become infected at any time). At time of writing there is one commercially available FIV vaccine in the United States; it causes positive antibody tests. As in FeLV infection, FIV vaccination won't be required in breeding, SPF, boarding catteries, or veterinary surgeries since there should be no opportunities for transmission in these environments.

Table 286-2
Use of In-House Feline Leukemia Virus and Feline Immunodeficiency Virus Tests in Different Cattery Types

Type of Cattery	Whether Cats are Tested	Action After Use of In-House Test
Boarding/quarantine	Not usually tested	
Rescue	Sometimes tested	Positive results <i>must</i> be confirmed since the cat may be euthanized. Negative results from testing a healthy animal are fine but from a sick animal should be confirmed.
Breeding	Always tested	Positive results likely to be false positive if pedigree cat from FeLV- and FIV-negative background; therefore confirm using gold standard test.*
Multicat pet household	Sometimes tested	Isolate cat and retest after 12 weeks. Confirm all positive results.
Veterinary premises	Rarely screened unless symptomatic	If symptomatic, negative results should be confirmed using gold standard test.*
Specific pathogen free	Always screened	Positive results likely to be false positive; therefore confirm using gold standard test.*

FeLV, Feline leukemia virus; FIV, feline immunodeficiency virus.
nB: FeLV vaccination does **not** affect in-house test results.
nB: FIV vaccination can cause positive antibody test results. FIV tests will detect maternally derived antibody until around 16 weeks of age in uninfected kittens of FIV-positive queens.
*Gold standard tests for FeLV are virus isolation and immunofluorescence. Gold standard tests for FIV are western blotting and immunofluorescence.

FELINE CORONAVIRUS/FELINE INFECTIOUS PERITONITIS

Feline coronavirus (FCoV) is an extremely infectious virus; over 90% of cats that encounter it seroconvert. FCoV is an RNA virus that mutates frequently. In the literature there are references to feline enteric coronavirus (FECV) as an avirulent FCoV responsible for the large number of seropositive cats in the absence of feline infectious peritonitis (FIP). However, it is now widely recognized that all strains of FCoV have the potential to cause FIP.

There are essentially two types of FCoV: type I is wholly feline; type II FCoVs arise by recombination with canine coronavirus (CCoV), and much of the spike of the type II FCoV is canine. About 90% of field isolates are type I; 10% are type II.

Feline Infectious Peritonitis Prevention and Feline Coronavirus Control

The key to prevention of FIP is to prevent FCoV infection. FCoV infection is perpetuated by a cycle of infection, virus shedding, development of immune response, loss of humoral immunity, and reinfection. In breeding catteries and ordinary pet households, control has been affected by excellent hygiene and by separating immunofluorescent antibody test (IFAT) seropositive and seronegative cats. Cats are tested every 3 to 6 months, and as their antibody titer falls they are put into a seronegative group, which is kept isolated from the seropositive group. Detection of virus is less useful, since cats can shed FCoV intermittently (see following paragraphs). The fewer cats in the cattery (or household), the better the chance of eliminating FCoV. Once a cattery is free of FCoV, all new cats should be antibody-tested negative before introduction.

Cat breeders should antibody test their cats for FCoV annually and only mate positive cats with other positive cats and negative cats with negative cats. Kittens of positive-to-positive cat matings can be prevented from becoming infected by early weaning and isolation.

FCoV is only shed transiently (a few days) in the saliva of a minority of cats. The main source of virus is the feces, and infection is by accidental ingestion of particulate feces (e.g., from grooming paws after using a litter tray or from airborne particles from a litter tray contaminating food). FCoV is a fragile virus, surviving only days outdoors, but it can survive indoors up to 7 weeks in dried feces in cat litter particles. See Chapter 285 and Box 286-1 for recommendations on minimizing exposure to FCoV. FCoV does not generally cross the placenta.

Vaccination

Experimental FIP vaccines have been plagued with the problem of inducing antibody-dependent enhanced disease (i.e., in which vaccinated cats are more likely to die of FIP than unvaccinated cats), and only a single FIP vaccine, Primucell (Pfizer) is commercially available. Primucell is a temperature-sensitive mutant that is instilled intranasally and gives rise to local immunoglobulin A and cell-mediated immunity. Primucell prevents FIP in 50% to 75% of cats that would have otherwise developed it but is ineffective in cats

Box 286-1

Protocol for Minimizing Feline Coronavirus Introduction or Spread in a Cattery*

- A. Reduce the numbers of cats in any area.
 - Ordinary house owners should keep no more than 6 to 10 cats.
 - Cats should be kept in stable groups of up to three or four.
 - In rescue facilities cats should be kept singly.
 - In an FCoV eradication program cats should be kept in small groups according to their antibody or virus excretion status.
 - Antibody- or virus-negative cats together
 - Antibody- or virus-positive cats together
- B. Avoid introducing virus to uninfected cats: antibody or virus testing.
 - Incumbent cats should be tested before introducing new cats or breeding.
 - Only antibody- or virus-negative cats should be introduced into FCoV-free catteries.
 - It is safer to introduce antibody-positive cats than antibody-negative cats into FCoV-infected households, but there is still a risk of FIP in both the newcomer and the incumbent cats.
- C. Prevent kitten infection: early weaning and isolation.
 - Both cat breeders and rescuers of pregnant cats should follow the protocol outlined in Table 286-2.
- D. Reduce fecal contamination of the environment.
 - Have adequate numbers of litter trays—at least one tray per cat.
 - Litter trays should be declumped at least daily.
 - Choose a nontracking cat litter.
 - Remove all litter and disinfect litter tray at least once a week.
 - Place litter trays away from the food area.
 - Vacuum around litter trays regularly.
 - Clip fur off hindquarters of long-haired cats.
- E. Vaccinate with Primucell.
 - If new cats must be introduced into a household with endemic infection, they should receive a full course of Primucell vaccine before introduction.
 - When economically possible, rescue catteries should vaccinate all new cats with Primucell.

FCoV, Feline coronavirus.

*Based on recommendations from working groups of the international feline enteric coronavirus and feline infectious peritonitis workshop. (From Pedersen NC, Addie D, Wolf A: Recommendations from working groups of the international feline enteric coronavirus and feline infectious peritonitis workshop, *Feline Pract* 23:108, 1995.)

previously exposed to FCoV. Thus in catteries wherein FCoV is endemic (most cat breeders' catteries), Primucell must be used in kittens that have already undergone a special management procedure known as early weaning and isolation so they are FCoV free when vaccinated. In addition, we know that Primucell vaccination does not prevent a cat from shedding FCoV (Addie, unpublished observations).

Feline Coronavirus Prevention in Kittens

Kittens are protected from FCoV infection by MDA, which wanes at around 5 to 6 weeks. This discovery has enabled the breeding of uninfected kittens even in households

in which FCoV is endemic and the queen is infected. Essentially the queen is isolated before giving birth in a single room or pen that has been well cleaned. The queen and litter are maintained in isolation with barrier nursing until the kittens are 5 to 6 weeks of age, when the queen is removed and the room thoroughly cleaned again. New clean litter trays are introduced. Detailed information about early weaning and isolation for owners is available on the Internet (www.catvirus.com), and a summary is given in Box 286-2.

Feline Coronavirus Tests

For control of FCoV to work, use of a reliable antibody test is essential. Samples split and sent to five different laboratories in the United States gave five completely different results (Postorino-Reeves, personal communication). The IFAT is the gold standard, but there is a risk of false positive results if antinuclear antibodies are present. IFA gives an antibody titer that is useful for comparison in sequential testing and should contain an internal negative control at each dilution.

RT-PCR detects the RNA of the FCoV. Detection of FCoV RNA in the blood or feces is not diagnostic of FIP, since many healthy animals or animals with non-FIP illness are also positive. Fecal RT-PCR is most useful in FCoV control as part of a series of tests; a single negative or positive test is usually meaningless. Determination of carrier cats requires nine monthly consecutive positive

fecal RT-PCR tests (this may change as quantitative RT-PCR becomes more widely available). Determination that a cat has eliminated FCoV infection requires five consecutive negative fecal RT-PCR tests or the return of the cat's antibody titer to less than 10.

Prevention of the Seropositive Cat From Developing Feline Infectious Peritonitis

Approximately 1 cat in 10 infected with FCoV develops FIP. Cats that have FCoV antibodies should not be stressed if at all possible (e.g., they should not be rehomed; neutering or any other operation that is not lifesaving should be delayed). If the owner has to leave the seropositive cat, having a "cat sitter" look after the cats in their own home is preferable to putting the cats into a cattery.

FELINE PARVOVIRUS, FELINE PANLEUKOPENIA, FELINE INFECTIOUS ENTERITIS, CANINE PARVOVIRUS

It is tempting to assume that feline parvovirus (FPV) (feline panleukopenia, feline infectious enteritis) is an infection of the past that has been more or less eradicated by vaccination. However, outbreaks are still ubiquitous wherever there are groups of susceptible cats and often manifest as sudden death or acute illness. FPV is the major cause of death of kittens under 4 months of age in rescue and breeding catteries and pet shops in the United Kingdom (Cave et al, 2002).

Unlike FPV, which has been recognized in cats for at least 100 years, canine parvovirus (CPV) type 2 emerged suddenly in the 1970s. CPV2 was subsequently replaced by antigenically variant viruses (CPV2a and CPV2b), which now coexist in dog populations worldwide. CPV2 isolates did not replicate in cats, but both CPV2a and CPV2b will. In a Japanese study about 10% of the virus isolates from cats with feline enteritis were found to be CPV2a or CPV2b. A third strain, CPV2c, isolated from leopard cats, can also infect domestic cats. Surprisingly, only 30% of parvoviruses from cheetahs and other large cats in zoos were FPV; the others were CPV.

Parvovirus is shed in feces but is also present in other secretions and can survive up to a year in the environment. Transmission of parvoviruses is mainly indirect; transplacental transmission also occurs. Despite the good acceptance of excellent vaccines by the cat-owning community, parvovirus manages to avoid extinction by subclinically infecting susceptible cats and kittens in whom it replicates. These cats shed huge amounts of viral particles for a few days to possibly weeks so that the environment becomes recontaminated. The virus can be transported on shoes or in cats' baskets to contaminate new environments so that even cats kept permanently indoors are not safe from infection. Thus cats in all types of catteries should be vaccinated. Live vaccines should not be used in pregnant queens because the virus can infect unborn kittens.

Attenuated live and inactivated vaccines are available against FPV and protect against both FPV and CPV2a, CPV2b, and CPV2c, but protection of inactivated vaccines is weaker against CPV types than against FPV. Most

Box 286-2

Protocol for Prevention of Feline Coronavirus Infection in Kittens

- Prepare kitten room
 - Remove all cats and kittens 1 week before introducing queen.
 - Disinfect room as far as possible using 1:32 dilution of sodium hypochlorite.
 - Dedicate litter trays, food and water bowls to this room and disinfect with sodium hypochlorite.
 - Introduce queen 1-2 weeks before she is due to give birth.
- Practice barrier nursing
 - Deal with the kitten room before tending other cats.
 - Clean hands with disinfectant before going into kitten room.
 - Have shoes and coveralls dedicated to the kitten room.
- Wean and isolate kittens early
 - Test queen for FCoV antibodies either before or after kitting.
 - If queen's antibody titer is greater than zero, the kittens should be removed to another clean room when they are 5-6 weeks old.
 - If the queen has an antibody titer of zero, she can remain with the kittens until they are older.
 - Take care to socialize isolated kittens to accustom them to humans during the 2-7-week-old period.
- Test kittens
 - Test kittens for FCoV antibodies at over 10 weeks of age.

FCoV, Feline coronavirus.

manufacturers recommend vaccination from 8 weeks of age onward, with a second dose at 12 weeks. A booster at 1 year of age is essential to cover cats in which the initial course was ineffective because of the presence of MDA.

MDA can persist until almost 20 weeks of age in kittens, particularly in those born to naturally exposed mothers who have very high antibody titers that interfere with vaccination and leave apparently vaccinated kittens susceptible to FPV. This is a problem in breeding catteries. Annual boosters are recommended by the manufacturer, but other than the first year, vaccination may not be absolutely necessary. There is evidence to suggest that immunity may persist; nine cats that were vaccinated with an inactivated FPV vaccine, kept in isolation, and given no boosters were challenged 7.5 years later and all still appeared to be immune (Scott and Geissinger, 1999).

When colostrum is not available, vaccination of newborn kittens is possible, and neutralizing antibodies appear at 7 to 12 days of age, indicating protection. However, live vaccines should not be used in kittens under 4 weeks of age or in pregnant queens because of the risk of cerebellar hypoplasia. Since FPV may only be shed for a matter of hours (sometimes as little as 36 hours), detection of the virus itself in cat feces is of limited value, and direct detection of FPV in the environment is currently not possible. Antibody testing of the sick cat can be more useful than detection of the virus itself. Antibodies to FPV can be detected by hemagglutination inhibition and enzyme-linked immunosorbent assay tests. For postmortem diagnosis of FPV, three 1-cm sections of different levels of the small intestine (duodenum, jejunum, and ileum) in 10% formol saline should be sent to a laboratory for histopathologic examination.

Advice for Rescue and Breeding Catteries and Pet Shops

Once parvovirus has occurred on the premises, the virus can be present for at least a year. Disinfection is difficult, with parvovirus resisting many disinfectants. Parvovirus is killed by sodium hypochlorite (domestic bleach). Disinfection with sodium hypochlorite (diluted 1:32) can reduce virus dose but will not eliminate the virus from soft furnishings. Since bleach is inactivated by organic material, thorough cleaning beforehand is vital for the success of disinfection. It is important to realize that infection is maintained in premises by subclinical infection of susceptible animals that become infected, produce huge amounts of virus, and then recover. Therefore susceptible animals are at risk if introduced within a year, and any new animals should have had a full course of vaccination, completed at least a week before being introduced.

To establish whether a cattery has parvovirus, some of the breeding animals should be tested for antibodies.

Antibody titers will be much higher in naturally exposed cats than in vaccinated cats. One option to prevent parvovirus is to stop breeding for a year so that no susceptible kittens are introduced.

Kittens are protected from parvovirus by MDA. The time over which antibody wanes can be calculated by halving the mother's antibody titer every 9.5 days of the offspring's life (97% of the queen's titer is found in the kitten). Thus if a queen had an antibody titer of 1024, at 9.5 days old the kitten's titer would be approximately 512, at 19 days 256, at 28.5 days 128, and so on (providing the kitten had suckled colostrum adequately). In this example, the kitten's titer would be 32 at 47.5 days. Thus the kitten should be rehomed to a parvovirus-free environment at that stage and vaccinated when its antibody titer has fallen to less than 10. Further vaccination of adult breeding stock is often pointless since many cats have a very high naturally acquired immunity, but it may be useful to screen all the breeding stock for antibodies and boost any cats that have very low antibody titers using a live vaccine (or inactivated vaccine if the cat is pregnant).

APPENDIX I

Table of Common Drugs: Approximate Dosages

MARK G. PAPICH, *Consulting Editor*

Drug Name	Other Names	Formulations Available	Dosage
Acepromazine	PromAce and many generic brands	5-, 10-, and 25-mg tablets and 10-mg/ml injection	Dog: 0.02-0.1 mg/kg IM, SC, IV; 0.56-2.25 mg/kg PO q6-8hr Cat: 0.02-0.1 mg/kg IM, SC, IV; or 1-2 mg/kg PO q8-12hr
Acetaminophen	Tylenol and many generic brands	120-, 160-, 325-, and 500-mg tablets	Dog: 15 mg/kg PO q8hr Cat: Not recommended
Acetaminophen with codeine	Tylenol with codeine and many generic brands	Oral solution and tablets. Many forms (e.g., 300 mg acetaminophen plus either 15, 30, or 60 mg codeine)	Follow dosing recommendations for codeine
Acetazolamide	Diamox	125- and 250-mg tablets	5-10 mg/kg PO q8-12hr (glaucoma) 4-8 mg/kg PO q8-12hr (other diuretic uses)
Acetylcysteine	Mucomyst	20% solution	Antidote: 140 mg/kg (loading dose) then 70 mg/kg IV or PO q4hr for five doses Eye: 2% solution topically q2hr
Acetylsalicylic acid	See Aspirin		
ACTH	See Corticotropin		
Activated charcoal	See Charcoal, activated		
Adequan	See Polysulfated glycosaminoglycan (PSGAG)		
Albendazole	Valbazen	113.6-mg/ml suspension and 300-mg/ml paste	25-50 mg/kg PO q12hr for 3 days For <i>Giardia</i> use 25 mg/kg q12hr for 2 days
Albuterol	Proventil or Ventolin	2-, 4-, and 5-mg tablets; 2 mg/5 ml syrup	20-50 mcg/kg q6-8hr; up to maximum of 100 mcg/kg q6-8hr PO
Allopurinol	Lopurin, Zyloprim	100- and 300-mg tablets	10 mg/kg q8hr, then reduce to 10 mg/kg q24hr
Aluminum carbonate gel	Basalgel	Capsule (equivalent to 500 mg aluminum hydroxide)	10-30 mg/kg PO q8hr (with meals)
Aluminum hydroxide gel	Amphojel	64-mg/ml oral suspension; 600-mg tablet	10-30 mg/kg PO q8hr (with meals)
Amikacin	Amiglyde-V (veterinary) and Amikin (human)	50- and 250-mg/ml injection	Dog: 15-30 mg/kg IV, SC, IM q24hr Cat: 10-14 mg/kg IV, SC, IM q24hr
Amiodarone	Cordarone	200-mg tablets; 50-mg/ml injection	Dog: Start with 15-mg/kg loading dose, then 10 mg/kg/day thereafter
Aminopentamide	Centrine	0.2-mg tablet; 0.5-mg/ml injection	Dog: 0.01-0.03 mg/kg IM, SC, PO q8-12hr Cat: 0.1 mg/cat IM, SC, PO q8-12hr

Drug Name	Other Names	Formulations Available	Dosage
Aminophylline	Many (generic) (Theophylline is preferred for oral therapy)	100- and 200-mg tablets; 25-mg/ml injection	Dog: 10 mg/kg PO, IM, IV q8hr Cat: 6.6 mg/kg PO q12hr
6-Aminosalicylic acid	See Mesalamine, Olsalazine		
Amitraz	Mitaban	10.6-ml concentrated dip (19.9%)	10.6 ml per 7.5 L water (0.025% solution). Apply three to six topical treatments q2wk. For refractory cases, this dose has been exceeded to produce increased efficacy. Doses that have been used include 0.025%, 0.05%, and 0.1% concentration applied twice per week and 0.125% solution applied to one-half body every day for 4 weeks to 5 months.
Amitriptyline	Elavil	10-, 25-, 50-, 75-, 100-, and 150-mg tablets; 10-mg/ml injection	Dog: 1-2 mg/kg PO q12-24hr (range: 0.25-4 mg/kg q12-24hr) Cat: 2-4 mg/cat/day PO; for cystitis: 2 mg/kg/day (2.5-7.5 mg/cat/day)
Amlodipine besylate	Norvasc	2.5-, 5-, and 10-mg tablets	Dog: 2.5 mg/dog or 0.1 mg/kg PO once daily Cat: 0.625 mg/cat/day PO initially and increase if needed to 1.25 mg/cat/day (average is 0.18 mg/kg)
Ammonium chloride	Generic	Available as crystals	Dog: 100 mg/kg PO q12hr Cat: 800 mg/cat (approximately $\frac{1}{3}$ to $\frac{1}{4}$ tsp) mixed with food daily
Amoxicillin trihydrate	Amoxi-Tabs, Amoxi-drops, Amoxil, and others	50-, 100-, 200-, and 400-mg tablets; 50-mg/ml oral suspension	6.6-20 mg/kg PO q8-12hr
Amoxicillin/clavulanic acid	Clavamox	62.5-, 125-, 250-, and 375-mg tablets; 62.5-mg/ml suspension	Dog: 12.5-25 mg/kg PO q12hr Cat: 62.5 mg/cat PO q12hr; consider administering these doses q8hr for gram-negative infections
Amphotericin B	Fungizone	50-mg injectable vial	0.5 mg/kg IV (slow infusion) q48hr, to a cumulative dose of 4-8 mg/kg
Amphotericin B (Liposomal)	Amphotec, Abelcet, AmBisome		Dog: 2-3 mg/kg IV 3 times/wk for 9-12 treatments for a cumulative dose of 24-27 mg/kg Cat: 1 mg/kg IV 3 times/wk for 12 treatments
Ampicillin	Omnipen, Principen, others	250-, and 500-mg capsules; 125-, 250-, and 500-mg vials of ampicillin sodium	10-20 mg/kg IV, IM, SC q6-8hr (ampicillin sodium) 20-40 mg/kg PO q8hr
Ampicillin + sulbactam	Unasyn	1.5- and 3-gm vials in 2:1 combination for injection	10-20 mg/kg IV, IM q8hr
Ampicillin trihydrate	Polyflex	10- and 25-mg vials for injection	Dog: 10-50 mg/kg SC, IM q24hr Cat: 10-20 mg/kg SC, IM q24hr
Amprolium	Amprol, Corid	9.6% (9.6 gm/dl) oral solution; soluble powder	1.25 gm of 20% amprolium powder to daily feed, or 30 ml of 9.6% amprolium solution to 3.8 L of drinking water for 7 days
Antacid drugs	See Aluminum hydroxide gel, Magnesium hydroxide, and Calcium carbonate		
Apomorphine hydrochloride	Generic	6-mg tablet	0.44 mg/kg IM; 0.05 mg/kg IV; 0.1 mg/kg SC, or instill 0.25 mg in conjunctiva of eye (dissolve 6-mg tablet in 1-2 ml of saline)
Ascorbic acid	Vitamin C	Various forms	100-500 mg/animal/day (diet supplement) or 100 mg/animal q8hr (urine acidification)

Continued

Appendix I—cont'd

Drug Name	Other Names	Formulations Available	Dosage
L-Asparaginase	Elspar	10,000 U per vial for injection	400 U/kg IV, IP, IM weekly; or 10,000 U/m ² weekly for 3 wk
Aspirin	Many generic and brand names (Bufferin, Ascriptin)	81-mg and 325-mg tablets	Dog: Mild analgesia: 10 mg/kg q12hr Antiinflammatory: 20-25 mg/kg q12hr Antiplatelet: 5-10 mg/kg q24-48hr Cat: 81 mg q48hr PO
Atenolol	Tenormin	25-, 50-, and 100-mg tablets; 25-mg/ml oral suspension; and 0.5-mg/ml ampule for injection	Dog: 6.25-12.5 mg/dog q12hr (or 0.25-1.0 mg/kg q12-24hr) PO Cat: 6.25-12.5 mg/cat q12hr (approximately 3 mg/kg) PO
Atipamezole	Antisedan	5-mg/ml injection	Inject same volume as used for medetomidine
Atracurium	Tracrium	10-mg/ml injection	0.2 mg/kg IV initially, then 0.15 mg/kg q30min (or IV infusion at 4-9 mcg/kg/min)
Atropine	Many generic brands	400-, 500-, and 540-mcg/ml injection; 15-mg/ml injection	0.02-0.04 mg/kg IV, IM, SC q6-8hr 0.2-0.5 mg/kg (as needed) for organophosphate and carbamate toxicosis
Auranofin (triethylphosphine gold)	Ridaura	3-mg capsule	0.1-0.2 mg/kg PO q12hr
Aurothioglucose	Solganol	50-mg/ml injection	Dog <10 kg: 1 mg IM first wk, 2 mg IM second wk, 1 mg/kg/wk maintenance Dog >10 kg: 5 mg IM first wk, 10 mg IM second wk, 1 mg/kg/wk maintenance Cat: 0.5-1 mg/cat IM q7 days
Azathioprine	Imuran	50-mg tablet; 10-mg/ml for injection	Dog: 2 mg/kg PO q24hr initially then 0.5-1 mg/kg q48hr Cat (use cautiously): 0.3 mg/kg PO q48hr
Azithromycin	Zithromax	250-mg capsule; and 250- and 600-mg tablets; 20-mg/ml oral suspension	Dog: 10 mg/kg PO q48hr or 3.3 mg/kg once daily Cat: 5-10 mg/kg PO every other day
AZT (azidothymidine)	See Zidovudine		
Bactrim (sulfamethoxazole + trimethoprim)	See Trimethoprim-sulfonamide combinations		
BAL	See Dimercaprol		
Benazepril	Lotensin	5-, 10-, 20-, and 40-mg tablets	Dog: 0.25-0.5 mg/kg PO q24hr Cat: 0.5-1 mg/kg q24hr PO or 2.5 mg/cat/day up to a maximum of 5 mg/cat/day
Betamethasone	Celestone	600-mcg (0.6-mg) tablet; 3-mg/ml sodium phosphate injection	0.1-0.2 mg/kg PO q12-24hr
Bethanechol	Urecholine	5-, 10-, 25-, and 50-mg tablets; 5-mg/ml injection	Dog: 5-15 mg/dog PO q8hr Cat: 1.25-5 mg/cat PO q8hr
Bisacodyl	Dulcolax	5-mg tablet	5 mg/animal PO q8-24hr
Bismuth subsalicylate	Pepto Bismol	Oral suspension: 262 mg/15 ml or 525 mg/ml in extra-strength formulation; 262-mg tablet	1-3 ml/kg/day (in divided doses) PO
Bleomycin	Blenoxane	15-U vials for injection	10 U/m ² IV or SC for 3 days, then 10 U/m ² weekly (maximum cumulative dose 200 U/m ²)
Bromide	See Potassium bromide		

Drug Name	Other Names	Formulations Available	Dosage
BSP (Bromsulphalein)	See Sulfobromophthalein (BSP)		
Budesonide	Entercort	3-mg capsule	Dog, cat: 0.125 mg/kg q6-8hr PO; dose interval may be increased to every 12 hr when condition improves
Bunamidine hydrochloride	Scolaban	400-mg tablet	20-50 mg/kg PO
Bupivacaine	Marcaine and generic	2.5- and 5-mg/ml solution injection	1 ml of 0.5% solution per 10 cm for an epidural
Buprenorphine	Temgesic (Vetergesic in the UK)	0.3-mg/ml solution	Dog: 0.006-0.02 mg/kg IV, IM, SC q4-8hr Cat: 0.005-0.01 mg/kg IV, IM q4-8hr Buccal administration in cats: 0.01-0.02 mg/kg q12hr
Buspirone	BuSpar	5- and 10-mg tablets	Dog: 2.5-10 mg/dog PO q12-24hr; or 1 mg/kg q12hr PO Cat: 2.5-5 mg/cat PO q24hr (may be increased to 5-7.5 mg/cat twice daily for some cats)
Busulfan	Myleran	2-mg tablet	3-4 mg/m ² PO q24hr
Butorphanol	Torbutrol Torbugesic	1-, 5-, and 10-mg tablets; 0.5- or 10-mg/ml injection	Dog: Antitussive: 0.055 mg/kg SC q6-12hr or 0.55 mg/kg PO Preanesthetic: 0.2-0.4 mg/kg IV, IM, SC (with acepromazine) Analgesic: 0.2-0.4 mg/kg IV, IM, SC q2-4hr or 0.55-1.1 mg/kg PO q6-12hr Cat: Analgesic: 0.2-0.8 mg/kg IV, SC q2-6hr, or 1.5 mg/kg PO q4-8hr
Calcitriol	Rocaltrol, Calcijex	Available as injection (Calcijex) and capsules (Rocaltrol): 0.25- and 0.5-mcg capsules; 1- or 2-mcg/ml injection	Dog: 0.25-0.5 mcg/dog/day or approx. 0.12 mg/kg Cat: 0.25 mcg/cat every other day; or 0.01-0.04 mcg/kg/day
Calcium carbonate	Many brands available: Titalac, Tums, generic	Many tablets or oral suspension (e.g., 650-mg tablet contains 260 mg calcium ion)	For phosphate binder: 60-100 mg/kg/day in divided doses PO For calcium supplementation: 70-180 mg/kg/day added to food
Calcium chloride	Generic	10% (100 mg/ml) solution	0.1-0.3 ml/kg IV (slowly)
Calcium citrate	Citracal (OTC)	950-mg tablet (contains 200 mg calcium ion)	Dog: 20 mg/kg/day added to food Cat: 10-30 mg/kg PO q8hr (with meals)
Calcium disodium EDTA	See Edetae calcium disodium		
Calcium gluconate	Kalcinate and generic	10% (100 mg/ml) injection	0.5-1.5 ml/kg IV (slowly)
Calcium lactate	Generic	OTC tablet	Dog: 0.5-2.0 gm/dog/day PO (in divided doses) Cat: 0.2-0.5 gm/cat/day PO (in divided doses)
Captopril	Capoten	25-mg tablet	Dog: 0.5-2 mg/kg PO q8-12hr Cat: 3.12-6.25 mg/cat PO q8hr
Carbenicillin	Geopen, Pyopen	1-, 2-, 5-, 10-, and 30-gm vials for injection	40-50 mg/kg and up to 100 mg/kg IV, IM, SC q6-8hr
Carbenicillin indanyl sodium	Geocillin	500-mg tablet	10 mg/kg PO q8hr
Carbimazole	Neo-mercazole	Available in Europe	Cat: 5 mg/cat PO q8hr (induction), followed by 5 mg/cat PO q12hr
Carboplatin	Paraplatin	50- and 150-mg vial for injection	Dog: 300 mg/m ² IV q3-4wk Cat: 200 mg/m ² IV q4wk

Drug Name	Other Names	Formulations Available	Dosage
Carprofen	Rimadyl (Zinecarp in the UK) Novox (generic)	25-, 75-, and 100-mg tablets 50 mg/ml solution	Dog: 2.2 mg/kg PO q12hr; or 4.4 mg/kg once daily PO; 2.2 mg/kg q12hr or 4.4 mg/kg once daily SC Cat: Doses not available
Carvedilol	Coreg	3.125-, 6.25-, 12.5-, and 25-mg tablets	Dog: 0.2 to 0.4 mg/kg q12hr PO; titrate dose up to 1.5 mg/kg q12hr PO if needed
Cascara sagrada	Many brands (e.g., Nature's Remedy)	100- and 325-mg tablets	Dog: 1-5 mg/kg day PO Cat: 1-2 mg/cat/day
Castor oil	Generic	Oral liquid (100%)	Dog: 8-30 ml/day PO Cat: 4-10 ml/day PO
Cefadroxil	Cefa-Tabs, Cefa-Drops	50-mg/ml oral suspension; 50-, 100-, 200-, and 1000-mg tablets	Dog: 22-30 mg/kg PO q12hr Cat: 22 mg/kg PO q24hr
Cefazolin sodium	Ancef, Kefzol, and generic	50 and 100 mg/50 ml for injection	20-35 mg/kg IV, IM q8hr For perisurgical use: 22 mg/kg q2hr during surgery
Cefdinir	Omnicef	300-mg capsules; 25-mg/ml oral suspension	Dose not established (human dose is 7 mg/kg PO q12hr)
Cefixime	Suprax	20-mg/ml oral suspension and 200- and 400-mg tablets	10 mg/kg PO q12hr For cystitis: 5 mg/kg PO q12-24hr
Cefotaxime	Claforan	500-mg and 1-, 2-, and 10-gm vials for injection	Dog: 50 mg/kg IV, IM, SC q12hr Cat: 20-80 mg/kg IV, IM q6hr
Cefotetan	Cefotan	1-, 2-, and 10-gm vials for injection	30 mg/kg IV, SC q8hr
Cefovecin	Convenia	80 mg/ml injection	Dog, cat: 8 mg/kg SC once every 14 days
Cefoxitin sodium	Mefoxin	1-, 2-, and 10-gm vials for injection	30 mg/kg IV q6-8hr
Cefpodoxime proxetil	Simplicef	100- and 200-mg tablets; 10- or 20-mg/ml human label suspension	Dog: 5-10 mg/kg PO once daily Cat: Dose not established
Ceftazidime	Fortaz, Ceptaz, Tazicef	0.5-, 1-, 2- and 6-gm vials reconstituted to 280 mg/ml	30 mg/kg IV, IM q6hr
Ceftiofur	Naxcel (ceftiofur sodium); Excenel (ceftiofur HCl)	50-mg/ml injection	2.2-4.4 mg/kg SC q24hr (for urinary tract infections)
Cephalexin	Keflex and generic forms	250- and 500-mg capsules; 250- and 500-mg tablets; 100-mg/ml or 125- and 250-mg/5-ml oral suspension	10-30 mg/kg PO q6-12hr; for pyoderma, 22-35 mg/kg PO q12hr
Cetirizine	Zyrtec	1-mg/ml oral syrup; 5- and 10-mg tablets	Dog: 5-10 mg/dog q12hr, PO, up to a dose of 2 mg/kg q12hr, PO Cat: 5 mg/cat, PO, q24hr
Charcoal, activated	ActaChar, Charcodote, Toxiban, generic	Oral suspension	1-4 gm/kg PO (granules) 6-12 ml/kg (suspension)
Chlorambucil	Leukeran	2-mg tablet	Dog: 2-6 mg/m ² or 0.1-0.2 mg/kg PO q24hr initially, then q48hr Cat: 0.1-0.2 mg/kg q24hr initially, then q48hr PO
Chloramphenicol and chloramphenicol palmitate	Chloromycetin, generic forms	30-mg/ml oral suspension (palmitate); 250-mg capsule; and 100-, 250-, and 500-mg tablets	Dog: 40-50 mg/kg PO q8hr Cat: 12.5-20 mg/kg PO q12hr
Chlorothiazide	Diuril	250- and 500-mg tablets; 50-mg/ml oral suspension and injection	20-40 mg/kg PO q12hr or IV
Chlorpheniramine maleate	Chlor-Trimeton, Phenetron, and others	4- and 8-mg tablets	Dog: 4-8 mg/dog PO q12hr (up to a maximum of 0.5 mg/kg q12hr) Cat: 2 mg/cat PO q12hr
Chlorpromazine	Thorazine	25-mg/ml injection solution	Dog: 0.5 mg/kg IM, SC q6-8hr (before cancer chemotherapy administer 2 mg/kg SC q3hr) Cat: 0.2-0.4 mg/kg q6-8hr IM, SC

Drug Name	Other Names	Formulations Available	Dosage
Chorionic gonadotropin	See Gonadotropin		
Cimetidine	Tagamet (OTC and prescription)	100-, 150-, 200-, and 300-mg tablets and 60-mg/ml injection	10 mg/kg IV, IM, PO q6-8hr (in renal failure administer 2.5-5 mg/kg IV, PO q12hr)
Ciprofloxacin	Cipro and generic	250-, 500-, and 750-mg tablets; 2-mg/ml injection	Dog: 10-20 mg/kg PO, IV q24hr Cat: Not recommended
Cisapride	Must be compounded		Dog: 0.1-0.5 mg/kg PO q8-12hr (doses as high as 0.5-1.0 mg/kg have been used in some dogs) Cat: 2.5-5 mg/cat PO q8-12hr (as high as 1 mg/kg q8hr has been administered to cats)
Cisplatin	Platinol	1-mg/ml injection; 50-mg vials	Dog: 60-70 mg/m ² q3-4wk (administer fluid for diuresis with therapy) Cat: Not recommended
Clavamox	See Amoxicillin-clavulanic acid combination		
Clavulanic acid	See Amoxicillin-clavulanic acid combination		
Clemastine	Tavist, Contac 12-hr allergy, and generic	1.34-mg tablet (OTC); 2.64-mg tablet (Rx); 0.134-mg/ml syrup	Dog: 0.05-0.1 mg/kg PO q12hr
Clindamycin	Antirobe, Cleocin, and generic	Oral liquid 25-mg/ml; 25-, 75-, 150-, and 300-mg capsule; and 150-mg/ml injection (Cleocin)	Dog: 11-33 mg/kg q12hr PO; for oral and soft tissue infection: 5.5-33 mg/kg q12hr PO Cat: 11-33 mg/kg q24hr PO for skin and anaerobic infections Toxoplasmosis: 12.5-25 mg/kg PO q12hr for 4 wks
Clofazimine	Lamprane	50- and 100-mg capsules	Cat: 1 mg/kg PO up to a maximum of 4 mg/kg/day
Clomipramine	Anafranil (human label); Clomicalm (veterinary label)	10-, 25-, and 50-mg tablets (human) 5-, 20-, and 80-mg tablets (veterinary)	Dog: 1-2 mg/kg PO q12hr up to a maximum of 3 mg/kg PO q12hr Cat: 1-5 mg/cat PO q12-24hr
Clonazepam	Klonopin	0.5-, 1-, and 2-mg tablets	Dog: 0.5 mg/kg PO q8-12hr Cat: 0.1-0.2 mg/kg q12-24hr PO
Clopidogrel	Plavix	75-mg tablets	Dog: 2-4 mg/kg q24hr PO; give oral loading dose of 10 mg/kg Cat: 19 mg per cat (¼ tablet) q24hr PO
Clorazepate	Tranxene	3.75-, 7.5-, 11.25-, 15-, and 22.5-mg, tablets	Dog: 2 mg/kg PO q12hr Cat: 0.2-0.4 mg/kg q12-24hr PO (up to 0.5-2 mg/kg)
Cloxacillin	Cloxapen, Orbenin, Tegopen	250- and 500-mg capsules; 25-mg/ml oral solution	20-40 mg/kg PO q8hr
Codeine	Generic	15-, 30-, and 60-mg tablets; 5-mg/ml syrup; 3-mg/ml oral solution	Analgesia: 0.5-1 mg/kg PO q4-6hr Antitussive: 0.1-0.3 mg/kg PO q4-6hr
Colchicine	Generic	500- and 600-mcg tablets; 500-mcg/ml ampule injection	0.01-0.03 mg/kg PO q24hr
Colony-stimulating factor	Sargramostim (Leukine) and Filgrastim (Neupogen)	300 mcg/ml (Neupogen) and 250 or 500 mcg/ml (Leukine)	Leukine: 0.25 mg/m ² q12hr SC or IV infusion Neupogen: 0.005 mg/kg (5 mcg/kg) q24hr SC for 2 wk
Corticotropin (ACTH)	Acthar	Gel 80 U/ml	Response test: Collect pre-ACTH sample and inject 2.2 IU/kg IM; collect post-ACTH sample in 2 hr in dogs and at 1 and 2 hr in cats

Appendix I—cont'd

Drug Name	Other Names	Formulations Available	Dosage
Cosequin	See Glucosamine chondroitin sulfate		
Cosyntropin	Cortrosyn	250 mcg per vial (can be stored in freezer for 6 months)	Response test: Dog: Collect pre-ACTH sample and inject 5 mcg/kg IV or IM and collect sample at 30 and 60 min Cat: 0.125 mg IV or IM and collect sample at 30 min and 60 min after IV administration and 30 and 60 min after IM administration
Cyanocobalamin (vitamin B ₁₂)	Many	100-mcg/ml injection	Dog: 100-200 mcg/day PO Cat: 50-100 mcg/day PO
Cyclophosphamide	Cytosan, Neosar	25-mg/ml injection; 25- and 50-mg tablets	Dog: Anticancer: 50 mg/m ² PO once daily 4 days/wk or 150-300 mg/m ² IV and repeat in 21 days Immunosuppressive therapy: 50 mg/m ² (approx. 2.2 mg/kg) PO q48hr or 2.2 mg/kg once daily for 4 days/wk Cat: 6.25-12.5 mg/cat once daily 4 days/wk
Cyclosporine (cyclosporin A)	Atopica, Neoral, Optimmune (ophthalmic)	Atopica: 10-, 25-, 50-, and 100-mg capsules Neoral: 25-mg and 100-mg microemulsion capsules; 100-mg/ml oral solution (for microemulsion) Optimmune: 0.2% ointment	Dog: 3-7 mg/kg/day; for atopic dermatitis some dogs are controlled with q48hr dosing Cat: 5 mg/kg PO q24hr
Cyropheptadine	Periactin	4-mg tablet; 2-mg/5-ml syrup	Antihistamine: 1.1 mg/kg PO q8-12hr Appetite stimulant: 2 mg/cat PO
Cytarabine (cytosine arabinoside)	Cytosar-U	100-mg vial	Dog (lymphoma): 100 mg/m ² IV, SC once daily or 50 mg/m ² twice daily for 4 days Cat: 100 mg/m ² once daily for 2 days
Dacarbazine	DTIC	200-mg vial for injection	200 mg/m ² IV for 5 days q3wk; or 800-1000 mg/m ² IV q3wk
Dalteparin	Fragmin	16 mg/0.2 ml; 32 mg/0.2 ml in prefilled syringes or 64 mg/ml multidose vials for injection	Dog: 100-150 units/kg q8hr SC Cat: 180 units/kg q6hr SC
Danazol	Danocrine	50-, 100-, and 200-mg capsules	5-10 mg/kg PO q12hr
Dantrolene	Dantrium	100-mg capsule and 0.33-mg/ml injection	For prevention of malignant hyperthermia: 2-3 mg/kg IV For muscle relaxation: Dog: 1-5 mg/kg PO q8hr Cat: 0.5-2 mg/kg PO q12hr
Dapsone	Generic	25- and 100-mg tablets	Dog: 1.1 mg/kg PO q8-12hr Cat: Do not use
Darbazine (prochlorperazine + isopropamide)	Darbazine	No. 1, 2, and 3 capsules	Dog, cat: 0.14-0.2 ml/kg SC q12hr Dog 2-7 kg: 1-#1 capsule PO q12hr Dog 7-14 kg: 1-#2 capsule PO q12hr Dog >14 kg: 1-#3 capsule PO q12hr
Deferoxamine	Desferal	500-mg vial for injection	10 mg/kg IV, IM q2hr for two doses; then 10 mg/kg q8hr for 24hr
Deprenyl (L-deprenyl)	See Selegiline (Anipryl)		
Deracoxib	Deramaxx	25-, 100-mg tablets	Dog: 3-4 mg/kg q24hr PO for 7 days; or 1-2 mg/kg q24hr PO for long-term use Cat: Dose not established

Drug Name	Other Names	Formulations Available	Dosage
Desmopressin acetate	DDAVP	100-mcg/ml injection and desmopressin acetate nasal solution (0.01% metered spray); 0.1- and 0.2-mg tablets	Diabetes insipidus: 2-4 drops (2 mcg) q12-24hr intranasally or in eye Animal oral dose: 0.05-0.1 mg/dog q12hr PO initially, then increase to 0.1-0.2 mg/dog q12hr as needed von Willebrand's disease treatment: 1 mcg/kg (0.01 ml/kg) SC, IV, diluted in 20 ml of saline administered over 10 min
Desoxycorticosterone pivalate	Percorten-V, DOCP, or DOCA pivalate	25 mg/ml injection	1.5-2.2 mg/kg IM q25days
Dexamethasone (dexamethasone solution and dexamethasone sodium phosphate)	Azium solution in polyethylene glycol. Sodium phosphate forms include Dexaject SP, Dexavet, and Dexasone. Tablets include Decadron and generic	Azium solution, 2 mg/ml. Sodium phosphate forms are 3.33 mg/ml; 0.25-, 0.5-, 0.75-, 1-, 1.5-, 2-, 4-, and 6-mg tablets	Antiinflammatory: 0.07-0.15 mg/kg IV, IM, PO q12-24hr Dexamethasone suppression test: Dog: 0.01 mg/kg IV Cat: 0.1 mg/kg IV Collect sample at 0, 4, and 8 hr
Dexmedetomidine	Dexdomitor	0.5-mg/ml injectable solution	Dog: Sedative and analgesic: 375 mg/m ² IV or 500 mg/m ² IM Dog: Preanesthetic: 125 mg/m ² IM Cat: Sedative and analgesic: 40 mcg/kg IM
Dextran	Dextran 70 Gentran-70	Injectable solution: 250, 500, and 1000 ml	10-20 ml/kg IV to effect
Dextromethorphan	Benylin and others	Available in syrup, capsule, and tablet; many OTC products	0.5-2 mg/kg PO q6-8hr has been reported, but effective dose not established
Dextrose solution 5%	DSW	Fluid solution for IV administration	40-50 ml/kg IV q24hr
Diazepam	Valium and generic	2- and 5-mg tablets; 5-mg/ml solution for injection	Preanesthetic: 0.5 mg/kg IV Status epilepticus: 0.5 mg/kg IV, 1.0 mg/kg rectal; repeat if necessary Appetite stimulant (cat): 0.2 mg/kg IV
Dichlorophen	Vermiplex (<i>See</i> Toluene)		
Dichlorphenamide	Daranide	50-mg tablet	3-5 mg/kg PO q8-12hr
Dichlorvos	Task	10- and 25-mg tablets	Dog: 26.4-33 mg/kg PO Cat: 11 mg/kg PO
Dicloxacillin	Dynapen	125-, 250-, and 500-mg capsules; 12.5-mg/ml oral suspension	25 mg/kg IM q6hr Oral doses not absorbed
Diethylcarbamazine (DEC)	Caricide, Filaribits	Chewable tablets; 50-, 60-, 180-, 200-, and 400-mg tablets	Heartworm prophylaxis: 6.6 mg/kg PO q24hr
Diethylstilbestrol (DES)	DES, generic (no longer manufactured in US)	1- and 5-mg tablet; 50-mg/ml injection	Dog: 0.1-1.0 mg/dog PO q24hr Cat: 0.05-0.1 mg/cat PO q24hr
Difloxacin	Dicural	11.4-, 45.4-, and 136-mg tablets	Dog: 5-10 mg/kg/day PO Cat: Safe dose not established
Digoxin	Lanoxin, Cardoxin	0.0625-, 0.125-, 0.25-mg tablets; 0.05- and 0.15-mg/ml elixir	Dog: <20 kg body weight: 0.01 mg/kg q12hr; >20 kg use 0.22 mg/m ² PO q12hr (subtract 10% for elixir) Dog: (rapid digitalization): 0.0055- 0.011 mg/kg IV q1hr to effect Cat: 0.008-0.01 mg/kg PO q48hr (approximately ¼ of a 0.125-mg tablet/cat)
Dihydrotychsterol (vitamin D)	Hytakerol, DHT	0.125-mg tablet; 0.5-mg/ml oral liquid	0.01 mg/kg/day PO; for acute treatment administer 0.02 mg/kg initially, then 0.01-0.02 mg/kg PO q24-48hr thereafter

Drug Name	Other Names	Formulations Available	Dosage
Diltiazem	Cardizem, Dilacor	30-, 60-, 90-, and 120-mg tablets; 50-mg/ml injection	Dog: 0.5-1.5 mg/kg PO q8hr, 0.25 mg/kg over 2 min IV (repeat if necessary) Cat: 1.75-2.4 mg/kg PO q8hr For Dilacor XR or Cardizem CD dose is 10 mg/kg PO once daily
Dimenhydrinate	Dramamine (Gravol in Canada)	50-mg tablets; 50-mg/ml injection	Dog: 4-8 mg/kg PO, IM, IV q8hr Cat: 12.5 mg/cat IV, IM, PO q8hr
Dimercaprol (BAL)	BAL in oil	Injection	4 mg/kg IM q4hr
Dinoprost tromethamine	See Prostaglandin F _{2α} 5-mg/ml injection		
Diethyl calcium sulfosuccinate	See Docusate calcium		
Diethyl sodium sulfosuccinate	See Docusate sodium		
Diphenhydramine	Benadryl	Available OTC: 2.5-mg/ml elixir; 25- and 50-mg capsules and tablets; 50-mg/ml injection	Dog: 25-50 mg/dog IV, IM, PO q8hr Cat: 2-4 mg/kg q6-8hr PO or 1 mg/kg IM, IV q6-8hr
Diphenoxylate	Lomotil	2.5 mg	Dog: 0.1-0.2 mg/kg PO q8-12hr Cat: 0.05-0.1 mg/kg PO q12hr
Diphenylhydantoin	See Phenytoin		
Diphosphonate disodium etidronate	See Etidronate disodium		
Dipyridamole	Persantine	25-, 50-, 75-mg tablets; 5-mg/ml injection	4-10 mg/kg PO q24hr
Dirlotapide	Slentrol	5-mg/ml oral oil-based solution	Dog: Start with 0.01 ml/kg/day PO Adjust by doubling the dose in 2 wks. Monthly adjustments to dose should be done on the basis of animal's weight loss. Do not exceed 0.2 ml/kg/day. Cat: Do not administer to cats
Disopyramide	Norpace (Rhythmolan in Canada)	100- and 150-mg capsules (10-mg/ml injection in Canada only)	6-15 mg/kg PO q8hr
Dithiazanine iodide	Dizan	10-, 50-, 100-, and 200-mg tablets	Heartworm: 6.6-11 mg/kg PO q24hr for 7-10 days For other parasites: 22 mg/kg PO
Divalproex sodium	See Valproic acid		
Dobutamine	Dobutrex	250-mg/20-ml vial for injection (12.5 mg/ml)	Dog: 5-20 mcg/kg/min IV infusion Cat: 2 mcg/kg/min IV infusion
Docusate calcium	Surfak, Doxidan	60-mg tablet (and many others)	Dog: 50-100 mg/dog PO q12-24hr Cat: 50 mg/cat PO q12-24hr
Docusate sodium	Colace, Doxan, Doss, many OTC brands	50-, and 100-mg capsules; 10-mg/ml liquid	Dog: 50-200 mg/dog PO q8-12hr Cat: 50 mg/cat PO q12-24hr
Dolasetron mesylate	Anzemet	50-, 100-mg tablets; 20-mg/ml injection	Dog, cat: Prevention of nausea and vomiting: 0.6 mg/kg IV or PO q24hr Treating vomiting and nausea: 1.0 mg/kg PO or IV once daily
Domperidone	Motilium	Not available in US	2-5 mg/animal PO
Dopamine	Intropin	40-, 80-, or 160-mg/ml	Dog, cat: 2-10 mcg/kg/min IV infusion
Doxapram	Dopram, Respiram	20-mg/ml injection	5-10 mg/kg IV Neonate: 1-5 mg SC, sublingual, or via umbilical vein

Drug Name	Other Names	Formulations Available	Dosage
Doxorubicin	Adriamycin	2-mg/ml injection	30 mg/m ² IV q21 days or >20 kg use 30 mg/m ² and <20 kg use 1 mg/kg Cat: 20 mg/m ² or approximately 1-1.25 mg/kg IV q3wk
Doxycycline	Vibramycin and generic forms	10-mg/ml oral suspension; 100-mg injection vial; 50- or 100-mg tablets or capsules	3-5 mg/kg PO, IV q12hr or 10 mg/kg PO q24hr For <i>Rickettsia</i> in dogs: 5 mg/kg q12hr
Edetate calcium disodium (CaNa ₂ EDTA)	Calcium disodium versenate	20-mg/ml injection	25 mg/kg SC, IM, IV q6hr for 2-5 days
Edrophonium	Tensilon and others	10-mg/ml injection	Dog: 0.11-0.22 mg/kg IV Cat: 0.25-0.5 mg/cat (total dose) IV
Enalapril	Enacard, Vasotec	2.5-, 5-, 10-, and 20-mg tablets	Dog: 0.5 mg/kg PO q12-24hr Cat: 0.25-0.5 mg/kg PO q12-24hr
Enflurane	Ethrane	Available as solution for inhalation	Induction: 2%-3% Maintenance: 1.5%-3%
Enilconazole	Imaverol, Clina-Farm-EC	10% or 13.8% emulsion	Nasal aspergillosis: 10 mg/kg q12hr instilled into nasal sinus for 14 days (10% solution diluted 50/50 with water) Dermatophytes: Dilute 10% solution to 0.2% and wash lesion with solution four times at 3- to 4-day intervals
Enoxaparin	Lovenox	30 mg/0.3 ml, 40 mg/0.4 ml, 60 mg/0.6 ml, 80 mg/0.8 ml, and 100 mg/1 ml in prefilled syringes for injection	Dog: 0.8 mg/kg SC q6hr Cat: 1.25 mg/kg SC q6hr
Enrofloxacin	Baytril	68-, 22.7-, and 5.7-mg tablets. Taste Tabs are 22.7 and 68 mg; 22.7-mg/ml injection	Dog: 5-20 mg/kg/day PO, IM Cat: 5 mg/kg/day PO (do not exceed dose)
Ephedrine	Many, generic	25- and 50-mg/ml injection	Vasopressor: 0.75 mg/kg, IM, SC; repeat as needed
Epinephrine	Adrenaline and generic forms	1-mg/ml (1:1,000) injection solution	Cardiac arrest: 10-20 mcg/kg IV or 200 mcg/kg intratracheal (may be diluted in saline before administration) Anaphylactic shock: 2.5-5 mcg/kg IV or 50 mcg/kg intratracheal (may be diluted in saline)
Epoetin alpha (Erythropoietin) (r-HuEPO)	Epogen, epoetin alfa (r-HuEPO)	2000-U/ml injection	Doses range from 35 or 50 U/kg three times/wk to 400 U/kg/wk IV, SC (adjust dose to hematocrit of 0.30-0.34) Cat: Start with 100 units/kg three times/wk and adjust dose based on hematocrit
Epsiprantel	Cestex	Coated tablet	Dog: 5.5 mg/kg PO Cat: 2.75 mg/kg PO
Ergocalciferol (vitamin D ₂)	Calciferol, Drisdol	400-U tablet (OTC); 50,000-U tablet (1.25 mg); 500,000-U/ml (12.5 mg/ml) injection	500-2000 U/kg/day PO
Erythromycin	Many brands and generic	250- or 500-mg capsule or tablet	Antibacterial dose: 10-20 mg/kg PO q8-12hr Prokinetic dose: 0.5-1.0 mg/kg PO q8hr

Appendix I—cont'd

Drug Name	Other Names	Formulations Available	Dosage
Esmolol	Brevibloc	10-mg/ml injection	500 mcg/kg IV, which may be given as 0.05-0.1 mg/kg slowly every 5 min or 50-200 mcg/kg/min infusion
Estradiol cypionate (ECP)	ECP, Depo-Estradiol, generic	2-mg/ml injection	Dog: 22-44 mcg/kg IM (total dose not to exceed 1.0 mg) Cat: 250 mcg/cat IM between 40 hr and 5 days of mating
Etidronate disodium	Didronel	200- and 400-mg tablets; 50-mg/ml injection	Dog: 5 mg/kg/day PO Cat: 10 mg/kg/day PO
Etodolac	EtoGesic, veterinary; Lodine, human	150- and 300-mg tablets	Dog: 10-15 mg/kg PO once daily Cat: Dose not established
Etretinate	Tegison	10- and 25-mg capsules	Dog: 1 mg/kg PO, with food/day or for <15 kg 10 mg/dog PO q24hr; >15 kg 10 mg/dog PO q12hr Cat: 2 mg/kg/day
Famotidine	Pepcid	10-mg tablet; 10-mg/ml injection	Dog: 0.1-0.2 mg/kg IM, SC, PO, IV q12hr; or 0.5 mg/kg PO q24hr, or 0.5 mg/kg IM, SC, PO, IV q24hr Cat: 0.2-0.25 mg/kg IM, IV, SC, PO q12-24hr
Felbamate	Felbatol	400- and 600-mg tablets; 120-mg/ml oral flavored suspension	Dog: Start with 15 mg/kg PO q8hr and increase gradually to maximum of 65 mg/kg q8hr
Fenbendazole	Panacur, Safe-Guard	Panacur granules 22.2% (222 mg/gm); 100-mg/ml liquid	50 mg/kg/day PO for 3 days
Fentanyl	Sublimaze, generic	50-mcg/ml injection	0.02-0.04 mg/kg IV, IM, SC q2hr or 0.01 mg/kg IV, IM, SC (with acetylpromazine or diazepam) For analgesia: 0.01 mg/kg IV, IM, SC q2hr
Fentanyl transdermal	Duragesic	25-, 50-, 75-, and 100-mcg/hr patch	Dog: 10-20 kg, 50-mcg/hr patch q72hr Cat: 25-mcg patch every 118hr
Ferrous sulfate	Many OTC brands	Many	Dog: 100-300 mg/dog PO q24hr Cat: 50-100 mg/cat PO q24hr
Finasteride	Proscar	5-mg tablets	Dog (BPH): 5-mg tablet/dog PO q24hr
Firocoxib	Previcox	57- or 227-mg tablets	Dog: 5 mg/kg PO, once daily Cat: 1.5 mg/kg, once; long-term safety in cats has not been determined
Florfenical	Nuflor	300 mg/ml (cattle)	Dog: 20 mg/kg q6hr PO, IM Cat: 22 mg/kg q12hr IM, PO
Fluconazole	Diflucan	50-, 100-, 150-, and 200-mg tablets; 10- or 40-mg/ml oral suspension; 2-mg/ml IV injection	Dog: 10-12 mg/kg day PO For malassezia 5 mg/kg q12hr PO Cat: 50 mg/cat PO q12hr or 50 mg/cat/day PO
Flucytosine	Ancobon	250-mg capsule; 75-mg/ml oral suspension	25-50 mg/kg PO q6-8hr (up to a maximal dose of 100 mg/kg PO q12hr)
Fludrocortisone	Florinef	100-mcg (0.1 mg) tablet	Dog: 0.2-0.8 mg/dog or 0.02 mg/kg PO q24hr (13-23 mcg/kg) Cat: 0.1-0.2 mg/cat PO q24hr
Flumazenil	Romazicon	100-mcg/ml (0.1 mg/ml) injection	0.2 mg (total dose) IV as needed
Flumethasone	Flucort	0.5-mg/ml injection	Dog, cat: Antiinflammatory: 0.15-0.3 mg/kg IV, IM, SC q12-24hr

Drug Name	Other Names	Formulations Available	Dosage
Flunixin meglumine	Banamine	250-mg packet granules; 10- and 50-mg/ml injection	1.1 mg/kg IV, IM, SC once or 1.1 mg/kg/day PO 3 days/wk Ophthalmic: 0.5 mg/kg IV once
5-Fluorouracil	Fluorouracil	50-mg/ml vial	Dog: 150 mg/m ² IV once/week Cat: Do not use
Fluoxetine	Prozac, Reconcile	8-, 16-, 32-, and 64-mg chewable tablets for dogs. Human formulation is 10- and 20-mg capsules and 4-mg/ml oral solution	Dog: 1-2 mg/kg/day PO q24hr Cat: 0.5-4 mg/cat PO q24hr
Follicle-stimulating hormone (FSM)	See Urofollitropin		
Fomepizole	4-Methylpyrazole, Antizole, and Antizol-vet	5% solution	Dog: 20 mg/kg initially IV, then 15 mg/kg at 12- and 24-hr intervals, then 5 mg/kg at 36hr; repeat q12hr if necessary
Furazolidone	Furoxone	100-mg tablet	4 mg/kg PO q12hr for 7-10 days
Furosemide	Lasix, generic	12.5-, 20-, and 50-mg tablets; 10-mg/ml oral solution; 50-mg/ml injection	Dog: 2-6 mg/kg IV, IM, SC, PO q8-12hr (or as needed) Cat: 1-4 mg/kg IV, IM, SC, PO q8-24hr
Gabapentin	Neurontin	100-, 300-, 400-mg capsules; 100-, 300-, 400-, 600-, 800-mg scored tablets; 50-mg/ml oral solution	Dog, cat: Anticonvulsant dose: 2.5-10 mg/kg q8-12hr PO For analgesia: 10-15 mg/kg q8hr PO
Gemfibrozil	Lopid	300-mg capsules; 600-mg tablets	7.5 mg/kg PO q12hr
Gentamicin	Gentocin	50- and 100-mg/ml solution for injection	Dog: 9-14 mg/kg IV, IM, SC q24hr Cat: 5-8 mg/kg IV, IM, SC q24hr
Glipizide	Glucotrol	5- and 10-mg tablets	Dog: Not recommended Cat: 2.5-7.5 mg/cat PO q12hr. Usual dose is 2.5 mg/cat initially, then increase to 5 mg/cat q12hr
Glucosamine chondroitin sulfate	Cosequin and others	Regular (RS) and double-strength (DS) capsules	Dog: 1-2 RS capsules/day (2-4 capsules of DS for large dogs) Cat: 1 RS capsule/day
Glyburide	Diabeta, Micronase, Glynase	1.25-, 2.5-, and 5-mg tablets	0.2 mg/kg/day PO; or 0.625 mg/cat
Glycerin	Generic	Oral solution	1-2 ml/kg, up to PO q8hr
Glycopyrrolate	Robinul-V	0.2-mg/ml injection	0.005-0.01 mg/kg IV, IM, SC
Gold sodium thiomalate	Myochrysine	10-, 25- and 50-mg/ml injection	1-5 mg IM on first wk, then 2-10 mg IM on second wk, then 1 mg/kg once/wk IM maintenance
Gold therapy	See Aurothioglucose, Gold sodium thiomalate, or Auranofin		
GoLYTELY	See Polyethylene glycol electrolyte solution		
Gonadorelin (GnRH, LHRH)	Factrel	50-mcg/ml injection	Dog: 50-100 mcg/dog/day IM q24-48hr Cat: 25 mcg/cat IM once
Gonadotropin, chorionic (HCG)	Profasi, Pregnyl, generic, A.P.L.	Injection sizes of 5,000, 10,000 and 20,000 U	Dog: 22 U/kg IM q24-48hr or 44 U IM once Cat: 250 U/cat IM once
Gonadotropin-releasing hormone	See Gonadorelin		
Granisetron	Kytril	1-mg/ml injection; 1-mg tablet	0.01 mg/kg (10 mcg/kg) IV
Griseofulvin (microsize)	Fulvicin U/F	125-, 250-, and 500-mg tablets; 25-mg/ml oral suspension; 125-mg/ml oral syrup	50 mg/kg PO q24hr (up to a maximum dose of 110-132 mg/kg/day in divided treatments)
Griseofulvin (ultramicrosize)	Fulvicin P/G, GrisPEG	100-, 125-, 165-, 250-, and 330-mg tablets	30 mg/kg/day in divided treatments PO

Appendix I—cont'd

Drug Name	Other Names	Formulations Available	Dosage
Growth hormone (hGH, somatrem, somatropin)	Protropin, Humatrope, Nutropin	5- and 10-mg/vial	0.1 U/kg SC, IM three times/wk for 4-6 wks (Usual human pediatric dose is 0.18-0.3 mg/kg/wk)
Guaifenesin	Glyceryl guaiacolate, Guaiphenesin, Mucinex	Tablets: 100-, 200-mg; 600-mg extended-release tablets Oral solution: 20 mg/ml or 40 mg/ml	Dog, cat: Expectorant: 3-5 mg/kg q8hr PO Dog: Anesthetic adjunct: 2.2 ml/kg/hr of a 5% solution IV
Halothane	Fulothane	250-ml bottle	Induction: 3% Maintenance: 0.5%-1.5%
Hemoglobin glutamer	Oxyglobin	13-gm/dl in 125-ml single-dose bags	Dog: One-time dose of 10-30 ml/kg IV at a rate not to exceed 10 ml/kg/hr Cat: One-time dose of 3-5 ml/kg slowly IV
Heparin sodium	Liquaemin (US); Hepalean (Canada)	1,000- and 10,000-U/ml injection	100-200 units/kg IV loading dose; then 100-300 units/kg SC q6-8hr Low-dose prophylaxis (dog and cat): 70 U/kg SC q8-12hr
Hetastarch	Hydroxyethyl starch (HES)	Injectable solution	Dog: 10-20 ml/kg/day IV Cat: 5-10 ml/kg/day IV
Hycodan	See Hydrocodone bitartrate		
Hydralazine	Apresoline	10-mg tablet; 20-mg/ml injection	Dog: 0.5 mg/kg (initial dose); titrate to 0.5-2 mg/kg PO q12hr Cat: 2.5 mg/cat PO q12-24hr
Hydrochlorothiazide	HydroDIURIL, and generic	10- and 100-mg/ml oral solution and 25-, 50-, and 100-mg tablets	2-4 mg/kg PO q12hr
Hydrocodone bitartrate	Hycodan	5-mg tablet; 1-mg/ml syrup	Dog: 0.22 mg/kg PO q4-8hr Cat: No dose available
Hydrocortisone	Cortef, and generic	5-, 10-, 20-mg tablets	Replacement therapy: 1-2 mg/kg PO q12hr Antiinflammatory: 2.5-5 mg/kg PO q12hr
Hydrocortisone sodium succinate	Solu-Cortef	Various size vials for injection	Shock: 50-150 mg/kg IV Antiinflammatory: 5 mg/kg IV q12hr
Hydromorphone	Dilaudid, Hydrostat, and generic	1-, 2-, 4-, 10-mg/ml injection Oral forms are available, but there is no assurance of oral absorption in dogs.	0.22 mg/kg IM or SC. Repeat every 4-6 hr, or as needed for pain treatment.
Hydroxyethyl starch (HES)	HES, Hetastarch	Injection	10-20 ml/kg IV to effect
Hydroxyurea	Hydrea	500-mg capsule	Dog: 50 mg/kg PO once daily, 3 days/wk Cat: 25 mg/kg PO once daily, 3 days/wk
Hydroxyzine	Atarax	10-, 25-, and 50-mg tablets; 2-mg/ml oral solution	Dog: 2 mg/kg q12hr PO, IV, IM Cat: Safe dose not established
Ibuprofen	Motrin, Advil, Nuprin	200-, 400-, 600-, and 800-mg tablets	Safe dose not established
Imipenem	Primaxin	250- or 500-mg vials for injection	3-10 mg/kg q6-8hr IV, SC, or IM; usually 5 mg/kg q6-8hr IM, IV, or SC q6-8hr
Imipramine	Tofranil	10-, 25-, and 50-mg tablets	Dog: 2-4 mg/kg PO q12-24hr Cat: 0.5-1.0 mg/kg q12-24hr PO
Indomethacin	Indocin		Safe dose has not been established

Drug Name	Other Names	Formulations Available	Dosage
Insulin, regular crystalline		100-U/ml injection	Ketoacidosis: animals <3 kg, 1 U/animal initially, then 1 U/animal q1hr; animals 3-10 kg, 2 U/animal initially, then 1 U/animal q1hr; animals >10 kg, 0.25 U/kg initially, then 0.1 U/kg IM q1hr
Insulin, NPH isophane, Ultralente, or PZI		100-U/ml injection	Dog <15 kg: 1 U/kg SC q24hr (to effect) Dog >25 kg: 0.5 U/kg SC q24hr (to effect) Cat: PZI or Ultralente initial dose 0.5-1.0 U/kg SC, usually twice/day
Interferon (interferon alpha, HuIFN-alpha)	Roferon	5- and 10-million U/vial	Dog: 2.5 million U/kg IV once daily for 3 days Cat: 1 million U/kg IV once daily for 5 consecutive days at 0, 14, and 60 days
Iodide	See Potassium iodide		
Ipecac syrup	Ipecac	Oral solution: 30-ml bottle	Dog: 3-6 ml/dog PO Cat: 2-6 ml/cat PO
Ipodate	Cholecystographic agent	50-mg capsules	Cat: 15 mg/kg q12hr PO (usually 50 mg/cat q12hr)
Iron	See Ferrous sulfate		
Isoflurane	AErrane	100-ml bottle	Induction: 5% Maintenance: 1.5%-2.5%
Isoproterenol	Isuprel	0.2-mg/ml ampules for injection	10 mcg/kg IM, SC q6hr; or dilute 1 mg in 500 ml of 5% dextrose or Ringer's solution and infuse IV 0.5-1 ml/min (1-2 mcg/min) or to effect
Isosorbide dinitrate	Isordil, Isorbid, Sorbitrate	2.5-, 5-, 10-, 20-, 30-, and 40-mg tablets; 40-mg capsules	2.5-5 mg/animal PO q12hr (or 0.22-1.1 mg/kg PO q12hr)
Isosorbide mononitrate	Monoket	10-, and 20-mg tablets	5 mg/dog PO two dose/day 7 hr apart
Isotretinoin	Accutane	10-, 20-, and 40-mg capsules	Dog: 1-3 mg/kg/day (up to a maximum recommended dose of 3-4 mg/kg/day PO) Cat: Dose not established
Itraconazole	Sporanox	100-mg capsules; 10-mg/ml oral solution	Dog: 2.5 mg/kg PO q12hr or 5 mg/kg PO q24hr For dermatophytes: 3 mg/kg/day PO for 15 days For Malassezia: 5 mg/kg q24hr PO for 2 days, repeated each wk for 3 wks Cat: 1.5-3.0 mg/kg, up to 5 mg/kg PO for 15 days
Ivermectin	Heartguard, Ivomec, Eqvalan liquid	1% (10 mg/ml) injectable solution; 10-mg/ml oral solution; 18.7-mg/ml oral paste; 68-, 136-, and 272-mcg tablets	Heartworm preventative: Dog: 6 mcg/kg PO q30 days Cat: 24 mcg/kg PO q30 days Microfilaricide: 50 mcg/kg PO 2 wks after adulticide therapy Ectoparasite therapy (dog and cat): 200-300 mcg/kg IM, SC, PO Endoparasites (dog and cat): 200-400 mcg/kg SC, PO weekly Demodex therapy: Start with 100 mcg/kg, then, increase to 600 mcg/kg/day PO for 60-120 days

Appendix I—cont'd

Drug Name	Other Names	Formulations Available	Dosage
Kanamycin	Kantrim	200- and 500-mg/ml injection	10 mg/kg IV, IM, SC q6-8hr; or 20 mg/kg q24hr IV, IM, SC
Kaopectate (kaolin + pectin)	Kaopectate	Oral suspension 12 oz	1-2 ml/kg PO q2-6hr
Ketamine	Ketalar, Ketavet, Vetalar	100-mg/ml injection solution	Dog: 5.5-22 mg/kg IV, IM (recommend adjunctive sedative or tranquilizer treatment) Cat: 2-25 mg/kg IV, IM (recommend adjunctive sedative or tranquilizer treatment)
Ketoconazole	Nizoral	200-mg tablet; 100-mg/ml oral suspension (only available in Canada)	Dog: 10-15 mg/kg PO q8-12hr For <i>Malassezia canis</i> infection use 5 mg/kg PO q24hr Hyperadrenocorticism: 15 mg/kg PO q12hr Cat: 5-10 mg/kg PO q8-12hr
Ketoprofen	Orudis-KT (human OTC tablet); Ketofen (veterinary injection)	12.5-mg tablet (OTC); 100-mg/ml injection	Dog, cat: 1 mg/kg PO q24hr for up to 5 days or 2.0 mg/kg IV, IM, SC for one dose
Ketorolac tromethamine	Toradol	10-mg tablet; 15- and 30-mg/ml injection in 10% alcohol	Dog: 0.5 mg/kg PO, IM, IV q12hr for not more than two doses
L-Dopa	See Levodopa		
Lactated Ringer's solution	Generic	250-, 500-, and 1,000-ml bags	Maintenance: 55-65 ml/kg/day IV For severe dehydration 50 ml/kg/hr IV or for shock 90 ml/kg IV (dogs) and 60-70 ml/kg IV (cats)
Lactulose	Chronulac, generic	10 gm/15 ml	Constipation: 1 ml/4.5 kg PO q8hr (to effect) Hepatic encephalopathy: Dog: 0.5 ml/kg PO q8hr Cat: 2.5-5 ml/cat PO q8hr
Leucovorin (folinic acid)	Wellcovorin and generic	5-, 10-, 15-, and 25-mg tablets; 3- and 5-mg/ml injection	With methotrexate administration: 3 mg/m ² IV, IM, PO Antidote for pyrimethamine toxicosis: 1 mg/kg PO q24hr
Levamisole	Levasole, Tamisol, Ergamisol	0.184-gm bolus; 11.7 gm/13-gm packet; 50-mg tablet (Ergamisol)	Dog (hookworms): 5-8 mg/kg PO once (up to 10 mg/kg PO for 2 days) Microfilaricide: 10 mg/kg PO q24hr for 6-10 days Immunostimulant: 0.5-2 mg/kg PO three times/wk Cat: 4.4 mg/kg once PO For lungworms: 20-40 mg/kg PO q48hr for five treatments
Levetiracetam	Keppra	250-, 500-, 750-mg tablets	Dog: Start with 20 mg/kg q8hr PO; increase gradually as necessary Cat: 30 mg/kg q12hr PO
Levodopa (L-dopa)	Larodopa, L-dopa	100-, 250-, and 500-mg tablets or capsules	Hepatic encephalopathy: 6.8 mg/kg initially then 1.4 mg/kg q6hr
Levothyroxine sodium (T ₄)	Soloxine, Thyro-Tabs, Synthroid	0.1- to 0.8-mg tablets (in 0.1-mg increments)	Dog: 18-22 mcg/kg PO q12hr (adjust dose via monitoring) Cat: 10-20 mcg/kg/day PO (adjust dose via monitoring)

Drug Name	Other Names	Formulations Available	Dosage
Lidocaine	Xylocaine and generic brands	5-, 10-, 15-, and 20-mg/ml injection	Antiarrhythmic: Dog: 2-4 mg/kg IV (to a maximum dose of 8 mg/kg over 10-min period); 25-75 mcg/kg/min IV infusion; 6 mg/kg IM q1.5hr Cat: 0.25-0.75 mg/kg IV slowly; or 10-40 mcg/kg/min infusion For epidural (dog and cat): 4.4 mg/kg of 2% solution
Lincomycin	Lincocin	100-, 200-, and 500-mg tablets	15-25 mg/kg PO q12hr For pyoderma: Doses as low as 10 mg/kg q12hr have been used
Linezolid	Zyvox	400- and 600-mg tablets; 20-mg/ml oral suspension; 2-mg/ml injection	Dog, cat: 10 mg/kg q8-12hr PO, IV
Liothyronine (T ₃)	Cytomel	60-mcg tablet	4.4 mcg/kg PO q8hr For T ₃ suppression test (cats): Collect presample for T ₄ and T ₃ ; administer 25 mcg q8hr for seven doses, then collect post samples for T ₃ and T ₄ after last dose
Lisinopril	Prinivil, Zestril	2.5-, 5-, 10-, 20-, and 40-mg tablets	Dog: 0.5 mg/kg PO q24hr Cat: No dose established
Lithium carbonate	Lithotabs	150-, 300-, and 600-mg capsules; 300-mg tablet; 300-mg/5 ml syrup	Dog: 10 mg/kg PO q12hr Cat: Not recommended
Lomotil	See Diphenoxylate		
Lomustine	CCNU, CeeNU	10-, 40-, 100-mg capsules	Dog: 70-90 mg/m ² , every 4 wks PO For brain tumors: Use 60-90 mg/m ² q6-8wk PO Cat: 50-60 mg/m ² PO q3-6 wk or 10 mg/cat PO every 3 wks
Loperamide	Imodium and generic	2-mg tablet; 0.2-mg/ml oral liquid	Dog: 0.1 mg/kg PO q8-12hr Cat: 0.08-0.16 mg/kg PO q12hr
Lufenuron	Program	45-, 90-, 135-, 204.9-, and 409.8-mg tablets; 135- and 270-mg suspension per unit pack	Dog: 10 mg/kg PO q30 days Cat: 30 mg/kg PO q30 days, 10 mg/kg SC q6mo
Lufenuron + milbemycin oxime	Sentinel tablets and Flavor Tabs	Milbemycin/lufenuron ratio is as follows: 2.3/46-mg tablets; 5.75/115-11.5/230-, and 23/460-mg Flavor Tabs	Administer 1 tablet q30 days; each tablet formulated for size of dog
Luteinizing hormone	See Gonadorelin		
L-Lysine	Enisyl-F	250-mg/ml paste	Paste formulation: 1-2 ml/cat, PO, to adult cats (approximately 400 mg/cat) and 1 ml/cat, PO, for kittens
Magnesium citrate	Citroma, Citro-Nesia (Citro-Mag in Canada)	Oral solution	2-4 ml/kg PO
Magnesium hydroxide	Milk of Magnesia	Oral liquid	Antacid: 5-10 ml/kg PO q4-6hr Cathartic: Dog: 15-50 PO ml/kg Cat: 2-6 ml/cat PO q24hr
Magnesium sulfate	Epsom salts	Crystals, many generic preparations	Dog: 8-25 gm/dog PO q24hr; for treating arrhythmias: 0.15-0.3 mEq/kg slowly IV over 5-15 min followed by 0.75-1.0 mEq/kg/day; fluid supplementation: 0.75-1.0 mEq/kg/day Cat: 2-5 gm/cat PO q24hr

Appendix I—cont'd

Drug Name	Other Names	Formulations Available	Dosage
Mannitol	Osmitol	5%-25% solution for injection	Diuretic: 1 gm/kg of 5%-25% solution IV to maintain urine flow Glaucoma or central nervous system edema: 0.25-2 gm/kg of 15%-25% solution IV over 30-60 min (repeat in 6 hr if necessary)
Marbofloxacin	Marbocyl, Zeniquim	25-, 50-, 100-, and 200-mg tablets	Dog, cat: 2.75-5.55 mg/kg PO q24hr
Maropitant	Cerenia	10-mg/ml injection; 16-, 24-, 60-, 160-mg tablets	Dog: 1 mg/kg SC once daily for up to 5 days; 2 mg/kg PO once daily for up to 5 days For motion sickness: 8 mg/kg PO once daily for up to 2 days Cat: Dose not established
MCT oil	MCT oil (many sources)	Oral liquid	1-2 ml/kg/day in food
Mebendazole	Telmintic	Each gram of powder contains 40 mg	22 mg/kg (with food) q24hr for 3 days
Meclizine	Antivert, generic	12.5-, 25-, and 50-mg tablets	Dog: 25 mg PO q24hr (for motion sickness, administer 1 hr before traveling) Cat: 12.5 mg PO q24hr
Meclofenamic acid (meclofenamate sodium)	Arquel, Meclomen	50- and 100-mg capsules	Dog: 1 mg/kg/day PO for up to 5 days Cat: Not recommended
Medetomidine	Domitor	1.0-mg/ml injection	750 mcg/m ² IV 1,000 mcg/m ² IM
Medium-chain triglycerides	See MCT oil		
Medroxyprogesterone acetate	Depo-Provera (injection); Provera (tablets)	150- and 400-mg/ml suspension injection; 2.5-, 5-, and 10-mg tablets	1.1-2.2 mg/kg IM q7 days; for behavioral use 10-20 mg/kg SC for prostate 3-5 mg/kg SC, IM
Megestrol acetate	Ovaban	5-mg tablet	Dog: Proestrus: 2 mg/kg PO q24hr for 8 days Anestrus: 0.5 mg/kg PO q24hr for 30 days Behavior: 2-4 mg/kg q24hr for 8 days (reduce dose for maintenance) Cat: Dermatologic therapy or urine spraying: 2.5-5 mg/cat PO q24hr for 1 wk, then reduce to 5 mg once or twice/wk Suppress estrus: 5 mg/cat/day for 3 days, then 2.5-5 mg once/wk for 10 wks
Melarsomine	Immiticide	25-mg/ml injection; after reconstitution retains potency for 24hr	Administer via deep IM injection. Class 1-2 dogs: 2.5 mg/kg/day for 2 consecutive days Class 3 dogs: 2.5 mg/kg once, then in 1 month two additional doses 24 hr apart
Meloxicam	Metacam (veterinary); Mobic (human)	Veterinary: 1.5-mg/ml oral suspension and 5-mg/ml injection Human: 7.5-mg tablets	Dog: 0.2 mg/kg initially PO, then 0.1 mg/kg q24hr PO thereafter; injection 0.1 mg/kg IV or SC Cat: 0.3 mg/kg SC one-time injection; 0.05 mg/kg q24-48hr PO for chronic use
Melphalan	Alkeran	2-mg tablet	1.5 mg/m ² (or 0.1-0.2 mg/kg) PO q24hr for 7-10 days (repeat every 3 wks)

Drug Name	Other Names	Formulations Available	Dosage
Meperidine	Demerol	50- and 100-mg tablets; 10-mg/ml syrup; 25-, 50-, 75-, and 100-mg/ml injection	Dog: 5-10 mg/kg IV, IM as often as q2-3hr (or as needed) Cat: 3-5 mg/kg IV, IM q2-4hr (or as needed)
Mepivacaine	Carbocaine-V	2% (20 mg/ml) injection	Variable dose for local infiltration. For epidural: 0.5 ml of 2% solution q30sec until reflexes are absent
6-Mercaptopurine	Purinethol	50-mg tablet	Dog: 50 mg/m ² PO q24hr Cat: Do not use
Meropenem	Merrem	500 mg in 20-ml vial, or 1-gm vial in 30-ml vial for injection	Dogs, cats: 8.5 mg/kg SC q12hr up to 12 mg/kg SC q12hr or 24 mg/kg IV q12hr
Mesalamine	Asacol, Mesasal, Pentasa	400-mg tablet; 250-mg capsule	Veterinary dose has not been established, the usual human oral dose is 400-500 mg q6-8hr (<i>also see</i> Sulfasalazine, Olsalazine)
Metaproterenol	Alupent, Metaprel	10- and 20-mg tablets; 5-mg/ml syrup; inhalers	0.325-0.65 mg/kg PO q4-6hr
Methadone	Methadose and generic	2-mg/ml oral solution; 10- and 20-mg/ml solution for injection; 5-, 10-, 40-mg tablets	Dog: 0.5-2.2 mg/kg IV, SC, IM, or 0.5-1.0 mg/kg IV q3-4hr for analgesia Cat: 0.2-0.5 mg/kg SC or IM, or 0.05-0.1 mg/kg up to 0.2 mg/kg IV q3-4hr for analgesia
Methazolamide	Neptazane	25- and 50-mg tablets	2-3 mg/kg PO q8-12hr
Methenamine hippurate	Hiprex, Urex	1-gm tablet	Dog: 500 mg/dog PO q12hr Cat: 250 mg/cat PO q12hr
Methenamine mandelate	Mandelamine and generic	1-gm tablet; granules for oral solution; 50- and 100-mg/ml oral suspension	10-20 mg/kg PO q8-12hr
Methimazole	Tapazole	5- and 10-mg tablets	Cat: 2.5 mg/cat q12hr PO for 7-14 days then 5-10 mg/cat PO q12hr and adjust by monitoring T ₄
DL-Methionine	See Racemethionine		
Methocarbamol	Robaxin-V	500- and 750-mg tablets; 100-mg/ml injection	44 mg/kg PO q8hr on the first day then 22-44 mg/kg PO q8hr
Methohexital	Brevital	0.5-, 2.5-, and 5-gm vials for injection	3-6 mg/kg IV (give slowly to effect)
Methotrexate	MTX, Mexate, Folex, Rheumatrex, generic	2.5-mg tablet; 2.5- or 25-mg/ml injection	2.5-5 mg/m ² PO q48hr (dose depends on specific protocol) or Dog: 0.3-0.5 mg/kg IV once/wk Cat: 0.8 mg/kg IV q2-3wk
Methoxamine	Vasoxyl	20-mg/ml injection	200-250 mcg/kg IM or 40-80 mcg/kg IV
Methoxyflurane	Metofane	4-oz bottle for inhalation	Induction: 3% Maintenance: 0.5%-1.5%
Methylene Blue 0.1%	Generic, also called New Methylene Blue	1% solution (10 mg/ml)	1.5 mg/kg IV, slowly
Methylprednisolone	Medrol	1-, 2-, 4-, 8-, 18-, and 32-mg tablets	0.22-0.44 mg/kg PO q12-24hr
Methylprednisolone acetate	Depo-Medrol	20- or 40-mg/ml suspension for injection	Dog: 1 mg/kg (or 20-40 mg/dog) IM q1-3wk Cat: 10-20 mg/cat IM q1-3wk
Methylprednisolone sodium succinate	Solu-Medrol	1- and 2-gm and 125- and 500-mg vials for injection	For emergency use: 30 mg/kg IV and repeat at 15 mg/kg IV in 2-6 hr
4-Methylpyrazole (fomepizole)	5% solution	Antizole, Antizol-Vet (Fomepizole)	See Fomepizol for dose

Appendix I—cont'd

Drug Name	Other Names	Formulations Available	Dosage
Methyltestosterone	Android, generic	10- and 25-mg tablets	Dog: 5-25 mg/dog PO q24-48hr Cat: 2.5-5 mg/cat PO q24-48hr
Metoclopramide	Reglan, Clopra, and others	5- and 10-mg tablets; 1-mg/ml oral solution; 5-mg/ml injection	0.2-0.5 mg/kg IV, IM, PO q6-8hr or IV loading dose at 0.4 mg/kg followed by 0.3 mg/kg/hr IV
Metoprolol tartrate	Lopressor	50- and 100-mg tablets; 1-mg/ml injection	Dog: 5-50 mg/dog (0.5-1.0 mg/kg) PO q8hr Cat: 2-15 mg/cat PO q8hr
Metronidazole and metronidazole benzoate	Flagyl and generic	250- and 500-mg tablets; 50-mg/ml suspension; 5-mg/ml injection; the benzoate form is not available commercially and must be obtained from a compounding pharmacist	For anaerobes: Dog: 15 mg/kg PO q12hr or 12 mg/kg q8hr Cat: 10-25 mg/kg PO q24hr For <i>Giardia</i> : Dog: 12-15 mg/kg PO q12hr for 8 days Cat: 17 mg/kg (1/3 tablet/cat) q24hr for 8 days
Mexiletine	Mexitil	150-, 200-, and 250-mg capsules	Dog: 5-8 mg/kg PO q8-12hr (use cautiously) Cat: Do not use
Mibolerone	Cheque-drops	55-mcg/ml oral solution	Dog: 0.45-11.3 kg, 30 mcg; 11.8-22.7 kg, 60 mcg; 23-45.3 kg, 120 mcg; >45.8 kg, 180 mcg; or approximately 2.6-5 mcg/kg/day PO Cat: Safe dose not established
Midazolam	Versed	5-mg/ml injection	Dog: 0.1-0.25 mg/kg IV, IM (or 0.1-0.3 mg/kg/hr IV infusion) Cat: 0.05 mg/kg IV; or 0.3-0.6 mg/kg IV (combine with 3 mg/kg ketamine)
Milbemycin oxime	Interceptor and Interceptor Flavor Tabs	23-, 11.5-, 5.75-, and 2.3-mg tablets	Dog: Microfilaricide; 0.5 mg/kg; Demodex: 2 mg/kg PO q24hr for 60-120 days Heartworm prevention: 0.5 mg/kg PO q30 days Cat: 2 mg/kg q30 days PO
Milk of Magnesia	See Magnesium hydroxide		
Mineral oil	Generic	Oral liquid	Dog: 10-50 ml/dog PO q12hr Cat: 10-25 ml/cat PO q12hr
Minocycline	Minocin	50-, 75-, and 100-mg tablets or capsules; 10-mg/ml oral suspension	5-12.5 mg/kg PO q12hr
Misoprostol	Cytotec	0.1-mg (100 mcg), 0.2-mg (200 mcg) tablets	Dog: 2-5 mcg/kg PO q6-8hr; for atopic dermatitis 5 mcg/kg q8hr PO Cat: Dose not established
Mithramycin	See Plicomycin (Mithracin)		
Mitotane (<i>o,p'</i> -DDD)	Lysodren	500-mg tablet	Dog: For pituitary-dependent hypercorticism: 50 mg/kg/day (in divided doses) PO for 5-10 days, then 50-70 mg/kg/wk PO For adrenal tumor: 50-75 mg/kg day for 10 days, then 75-100 mg/kg/wk PO
Mitoxantrone	Novantrone	2-mg/ml injection	Dog: 6 mg/m ² IV q21 days Cat: 6.5 mg/m ² IV q21 days

Drug Name	Other Names	Formulations Available	Dosage
Morphine	Generic	1- and 15-mg/ml injection; 30- and 60-mg delayed-release tablets	Dog: 0.1-1 mg/kg IV, IM, SC (dose is escalated as needed for pain relief) q4-6hr; Dog: 0.5 mg/kg q2hr IV, IM, or CRI 0.2 mg/kg followed by 0.1 mg/kg/hr IV Epidural: 0.1 mg/kg Cat: 0.1 mg/kg q3-6hr IM, SC (or as needed)
Moxidectin	Cydectin	Injection	Dog: Heartworm prevention: 3 mcg/kg Endoparasites: 25-300 mcg/kg Demodex: 400 mcg/kg/day up to 500 mcg/kg/day for 21-22 wks
Moxifloxacin	Avelox	400-mg tablet	10mg/kg q24hr PO
Mycochrysin	See Gold sodium thiomalate		
Mycophenolate	Cell Cept	250-mg capsule	Dog: 10 mg/kg q8hr PO Cat: No dose established
Naloxone	Narcan	20- or 400-mcg/ml injection	0.01-0.04 mg/kg IV, IM, SC as needed to reverse opiate
Naltrexone	Trexan	50-mg tablet	For behavior problems: 2.2 mg/kg PO q12hr
Nandrolone decanoate	Deca-Durabolin	Nandrolone decanoate injection: 50-, 100-, and 200-mg/ml	Dog: 1-1.5 mg/kg/wk IM Cat: 1 mg/cat/wk IM
Naproxen	Naprosyn, Naxen, Aleve (naproxen sodium)	220-mg tablet (OTC); 25-mg/ml suspension liquid; 250-, 375-, and 500-mg tablets (Rx)	Dog: 5 mg initially, then 2 mg/kg q48hr Cat: Not recommended
Neomycin	Biosal	500-mg bolus; 200-mg/ml oral liquid	10-20 mg/kg PO q6-12hr
Neostigmine bromide and neostigmine methylsulfate	Prostigmin; Stiglyn	15-mg tablet (neostigmine bromide); 0.25- and 0.5-mg/ml injection (neostigmine methylsulfate)	2 mg/kg/day PO (in divided doses, to effect) Injection: Antimyasthenic: 10 mcg/kg IM, SC, as needed Antidote for nondepolarizing neuromuscular block: 40 mcg/kg IM, SC Diagnostic aid for myasthenia gravis: 40 mcg/kg IM or 20 mcg/kg IV
Nifedipine	Adalat, Procardia	10- and 20-mg capsules	Dose not established; in humans, the dose is 10 mg/human three times/day and increased in 10-mg increments to effect
Nitenpyram	Capstar	11.4- or 57-mg tablet	1 mg/kg PO daily as needed to kill fleas
Nitrates	See Nitroglycerin, Isosorbide dinitrate, or Nitroprusside		
Nitrofurantoin	Macrochantin, Furalan, Furatoin, Furadantin, or generic	Macrochantin and generic 25-, 50-, and 100-mg capsules; Furalan, Furatoin, and generic 50- and 100-mg tablets; Furadantin 5-mg/ml oral suspension	10 mg/kg/day divided into four daily treatments, then 1 mg/kg PO at night
Nitroglycerin ointment	Nitrol, Nitro-Bid, Nitrostat	0.5-, 0.8-, 1-, 5-, and 10-mg/ml injection; 2% ointment; transdermal systems (0.2 mg/hr patch)	Dog: 4-12 mg (up to 15 mg) topically q12hr Cat: 2-4 mg topically q12hr (or ¼ inch of ointment per cat)
Nitroprusside	Nitropress	50-mg vial for injection	1-5, up to a maximum of 10 mcg/kg/min IV infusion
Nizatidine	Axid	150- and 300-mg capsules	Dog: 5 mg/kg PO q24hr
Norfloxacin	Noroxin	400-mg tablet	22 mg/kg PO q12hr
o,p'-DDD	See Mitotane (Lysodren)		

Continued

Appendix I—cont'd

Drug Name	Other Names	Formulations Available	Dosage
Olsalazine	Dipentum	500-mg tablet	Dose not established (usual human dose is 500 mg or 5-10 mg/kg PO twice daily)
Omeprazole	Prilosec (formerly Losec), Gastrogard (equine paste)	20-mg capsule	Dog: 20 mg/dog PO once daily (or 0.7 mg/kg q24hr) Cat: 0.5-0.7 mg/kg q24hr PO
Ondansetron	Zofran	4- and 8-mg tablets; 2-mg/ml injection	0.5-1.0 mg/kg IV, PO 30 minutes before administration of cancer drugs
Orbifloxacin	Orbax	5.7-, 22.7-, and 68-mg tablets	2.5-7.5 mg/kg PO once daily
Ormetoprim	See Primor (ormetoprim-sulfadimethoxine)		
Oxacillin	Prostaphlin and generic	250- and 500-mg capsules; 50-mg/ml oral solution	22-40 mg/kg PO q8hr
Oxazepam	Serax	15-mg tablet	Cat: Appetite stimulant: 2.5 mg/cat PO
Oxtriphylline	Choledyl-SA	400- and 600-mg tablet (oral solutions and syrup available in Canada but not US)	Dog: 47 mg/kg (equivalent to 30 mg/kg theophylline) PO q12hr
Oxybutynin chloride	Ditropan	5-mg tablet	Dog: 5 mg/dog PO q6-8hr
Oxymetholone	Anadrol	50-mg tablet	1-5 mg/kg/day PO
Oxymorphone	Numorphan	1.5- and 1-mg/ml injection	Dog, cat: Analgesia: 0.1-0.2 mg/kg IV, SC, IM (as needed), redose with 0.05-0.1 mg/kg q1-2hr Preanesthetic: 0.025-0.05 mg/kg IM, SC
Oxytetracycline	Terramycin	250-mg tablets; 100- and 200-mg/ml injection	7.5-10 mg/kg IV q12hr; 20 mg/kg PO q12hr
Oxytocin	Pitocin and Syntocinon (nasal solution) and generic	10- and 20-U/ml injection; 40-U/ml nasal solution	Dog: 5-20 U/dog SC, IM (repeat every 30 min for primary inertia) Cat: 2.5-3 U/cat SC, IM (repeat every 30 min)
2-PAM	See Pralidoxime chloride		
Pamidronate	Aredia	30-, 60-, 90-mg vials for injection	Dog: 2 mg/kg IV, SC For treatment of cholecalciferol tox- icosis: 1.3-2 mg/kg for two treatments
Pancreatic enzyme	See Pancrelipase		
Pancrelipase	Viokase	16,800 U of lipase, 70,000 U of protease, and 70,000 U of amylase per 0.7 gm; also capsules and tablets	Mix 2 tsp powder with food per 20 kg body weight or 1-3 tsp/0.45 kg of food 20 min before feeding
Pancuronium bromide	Pavulon	1- and 2-mg/ml injection	0.1 mg/kg IV or start with 0.01 mg/kg and additional 0.01-mg/kg doses every 30 min
Pantoprazole	Protonix	40-mg tablets, 0.4-mg/ml vials for injection	Dog, cat: 0.5 mg/kg q24hr IV or 0.5-1 mg/kg IV infusion over 24 hr
Paregoric	Corrective mixture	2 mg morphine per 5 ml of paregoric	0.05-0.06 mg/kg PO q12hr
Paroxetine	Paxil	10-, 20-, 30-, and 40-mg tablets	Cat: 1/8 to 1/4 of a 10-mg tablet daily PO
D-Penicillamine	Cuprimine, Depen	125- and 250-mg capsules and 250-mg tablets	10-15 mg/kg PO q12hr
Penicillin G benzathine	Benza-pen and other names	150,000 U/ml, combined with 150,000 U/ml of procaine penicillin G	24,000 U/kg IM q48hr
Penicillin G potassium; penicillin G sodium	Many brands	5- to 20-million unit vials	20,000-40,000 U/kg IV, IM q6-8hr

Drug Name	Other Names	Formulations Available	Dosage
Penicillin G procaine	Generic	300,000 U/ml suspension	20,000-40,000 U/kg IM q12-24hr
Penicillin V	Pen-Vee	250- and 500-mg tablets	10 mg/kg PO q8hr
Pentobarbital	Nembutal and generic	50 mg/ml	25-30 mg/kg IV to effect; or 2-15 mg/kg IV to effect, followed by 0.2-1.0 mg/kg/hr IV
Pentoxifylline	Trental	400-mg tablet	Dog: For use in canine dermatology and for vasculitis, 10 mg/kg PO q12hr and up to 15 mg/kg q8hr Cat: ¼ of 400-mg tab PO, q8-12hr
Pepto Bismol	See Bismuth subsalicylate		
Phenobarbital	Luminal and generic	15-, 30-, 60-, and 100-mg tablets; 30-, 60-, 65-, and 130-mg/ml injection; 4-mg/ml oral elixir solution	Dog: 2-8 mg/kg PO q12hr Cat: 2-4 mg/kg PO q12hr Dog and cat: Adjust dose by monitoring plasma concentration Status epilepticus: Administer in increments of 10-20 mg/kg IV (to effect)
Phenoxybenzamine	Dibenzylamine	10-mg capsule	Dog: 0.25 mg/kg PO q8-12hr or 0.5 mg/kg q24hr Cat: 2.5 mg/cat q8-12hr or 0.5 mg/cat PO q12hr (in cats, doses as high as 0.5 mg/kg IV have been used to relax urethral smooth muscle)
Phentolamine	Regitine (Rogitine in Canada)	5-mg vial for injection	0.02-0.1 mg/kg IV
Phenylbutazone	Butazolidin and generic	100-, 200-, 400-mg and 1-gm tablets; 200-mg/ml injection	Dog: 15-22 mg/kg PO, IV q8-12hr (44 mg/kg/day) (800 mg/dog maximum) Cat: 6-8 mg/kg IV, PO q12hr
Phenylephrine	Neo-Synephrine	10-mg/ml injection; 1% nasal solution	0.01 mg/kg IV q15min 0.1 mg/kg IM, SC q15min
Phenylpropanolamine	PPA, Propalin, Proin PPA	25-, 50-, and 75-mg tablets and 25-mg/ml liquid	Dog: 1 mg/kg q12hr, PO and increase to 1.5-2.0 mg/kg as needed q8hr PO
Phenytoin	Dilantin	30- and 125-mg/ml oral suspension; 30- and 100-mg capsules; 50-mg/ml injection	Antiepileptic dog: 20-35 mg/kg q8hr Antiarrhythmic: 30 mg/kg PO q8hr or 10 mg/kg IV over 5 min
Physostigmine	Antilirium	1-mg/ml injection	0.02 mg/kg IV q12hr
Phytomenadione	See Vitamin K ₁		
Phytonadione	See Vitamin K ₁		
Pimobendan	Vetmedin	2.5- and 5-mg capsules (Europe and Canada); 1.25-, 2.5-, 5-mg chewable tablets (US)	Dog: 0.05 mg/kg/day in divided treatments q12hr Cat: Dose not established
Piperacillin	Pipracil	2-, 3-, 4-, and 40-gm vials for injection	40 mg/kg IV or IM q6hr
Piperazine	Many	860-mg powder; 140-mg capsule, 170-, 340-, and 800-mg/ml oral solution	44-66 mg/kg PO administered once
Piroxicam	Feldene and generic	10-mg capsule	Dog: 0.3 mg/kg PO q48hr Cat: 0.3 mg/kg q24hr PO
Pitressin (ADH)	See Vasopressin, Desmopressin acetate		
Plicamycin (old name is mithramycin)	Mithracin	2.5-mg injection	Dog: Antineoplastic: 25-30 mcg/kg day IV (slow infusion) for 8-10 days Antihypercalcemic: 25 mcg/kg/day IV (slow infusion) over 4 hr Cat: Not recommended

Continued

Appendix I—cont'd

Drug Name	Other Names	Formulations Available	Dosage
Polyethylene glycol electrolyte solution	GoLYTELY	Oral solution	25 ml/kg PO repeat in 2-4 hr PO
Polysulfated glycosaminoglycan (PSGAG)	Adequan Canine	100-mg/ml injection in 5-ml vial (for horses vials are 250 mg/ml)	4.4 mg/kg IM twice weekly for up to 4 wks
Potassium bromide (KBr)	No commercial formulation	Usually prepared as oral solution Must be compounded	Dog and cat: 30-40 mg/kg PO q24hr If administered without phenobarbital, higher doses of up to 40-50 mg/kg may be needed. Adjust doses by monitoring plasma concentrations. Loading doses of 600-800 mg/kg divided over 3-4 days have been administered.
Postassium chloride (KCl)	Generic	Various concentrations for injection (usually 2 mEq/ml); oral suspension and oral solution	0.5 mEq potassium/kg/day; or supplement 10-40 mEq/500 ml of fluids, depending on serum potassium
Postassium citrate	Generic, Urocit-K	5-mEq tablet; some forms are in combination with postassium chloride	0.5 mEq/kg/day PO
Potassium gluconate	Kaon, Tumil-K, generic	2-mEq tablet; 500-mg tablet; Kaon elixir is 20-mg/15-ml elixir	Dog: 0.5 mEq/kg PO q12-24hr Cat: 2-8 mEq/day PO divided twice daily
Postassium iodide			30-100 mg/cat daily (in single or divided doses) for 10-14 days
Pralidoxime chloride (2-PAM)	2-PAM, Protopam Chloride	50-mg/ml injection	20 mg/kg q8-12hr (initial dose) IV slow or IM
Praziquantel	Droncit	23- and 34-mg tablets; 56.8-mg/ml injection	Dog (PO): <6.8 kg, 7.5 mg/kg, once; >6.8 kg, 5 mg/kg, once (IM, SC): <2.3 kg, 7.5 mg/kg, once; 2.7-4.5 kg, 6.3 mg/kg, once; >5 kg, 5 mg/kg, once Cat (PO): <1.8 kg, 6.3 mg/kg, once; >1.8 kg, 5 mg/kg, once (for <i>Paragonimus</i> use 25 mg/kg q8hr for 2-3 days) (IM, SC): 5 mg/kg
Prazosin	Minipress	1-, 2-, and 5-mg capsules	0.5- and 2-mg/animal (1 mg/15 kg) PO q8-12hr
Prednisolone	Delta-Cortef and many others	5- and 20-mg tablets	Dog (cat often requires two times dog dose) Antiinflammatory: 0.5-1 mg/kg IV, IM, PO q12-24hr initially, then taper to q48hr Immunosuppressive: 2.2-6.6 mg/kg/day IV, IM, PO initially, then taper to 2-4 mg/kg q48hr Replacement therapy: 0.2-0.3 mg/kg/day PO
Prednisolone sodium succinate	Solu-Delta-Cortef	100- and 200-mg vials for injection (10 and 50 mg/ml)	Shock: 15-30 mg/kg IV (repeat in 4-6 hr) Central nervous system trauma: 15-30 mg/kg IV, taper to 1-2 mg/kg q12hr
Prednisone	Deltasone and generic; Meticorten for injection	1-, 2.5-, 5-, 10-, 20-, 25-, and 50-mg tablets; 1-mg/ml syrup (LiquidPred in 5% alcohol) and 1-mg/ml oral solution (in 5% alcohol); 10- and 40-mg/ml prednisone suspension for injection	Same as prednisolone, except that prednisone is not recommended for cats

Drug Name	Other Names	Formulations Available	Dosage
Primidone	Mylepsin, Neurosyn (Mysoline in Canada)	50- and 250-mg tablets	8-10 mg/kg PO q8-12hr as initial dose, then is adjusted via monitoring to 10-15 mg/kg q8hr
Primor (ormetoprim + sulfadimethoxine)	Primor	Combination tablet (ormetoprim + sulfadimethoxine)	27 mg/kg on first day, followed by 13.5 mg/kg PO q24hr
Procainamide	Pronestyl, generic	250-, 375-, 500-mg tablets or capsules; 100- and 500-mg/ml injection	Dog: 10-30 mg/kg PO q6hr (to a maximum dose of 40 mg/kg), 8-20 mg/kg IV IM; 25-50 mcg/kg/min IV infusion Cat: 3-8 mg/kg IM, PO q6-8hr
Prochlorperazine	Compazine	5-, 10-, and 25-mg tablets (prochlorperazine maleate); 5-mg/ml injection (prochlorperazine edisylate)	0.1-0.5 mg/kg IM, SC q6-8hr
Progesterone, repositol	See Medroxyprogesterone acetate		
Promethazine	Phenergan	6.25- and 25-mg/5-ml syrup; 12.5-, 25-, 50-mg tablets; 25- and 50-mg/ml injection	0.2-0.4 mg/kg IV, IM PO q6-8hr (up to a maximum dose of 1 mg/kg)
Propantheline bromide	Pro-Banthine	7.5- and 15-mg tablet	0.25-0.5 mg/kg PO q8-12hr
Propiomazine	Tranvet	5-, 10-mg/ml injection or 20-mg tablet	1.1-4.4 mg/kg q12-24hr PO or 0.1-1.1 mg/kg IM, IV (range of dose depends on degree of sedation needed)
Propofol	Rapinivet and PropoFlo (veterinary); Diprivan (human)	1% (10 mg/ml) injection in 20-ml ampules	6.6 mg/kg IV slowly over 60 seconds; constant-rate IV infusions have been used at 5 mg/kg slowly IV, followed by 100-400 mcg/kg/min IV
Propranolol	Inderal	10-, 20-, 40-, 60-, 80-, and 90-mg tablets; 1-mg/ml injection; 4- and 8-mg/ml oral solution	Dog: 20-60 mcg/kg over 5-10 min IV; 0.2-1 mg/kg PO q8hr (titrate dose to effect) Cat: 0.4-1.2 mg/kg (2.5-5 mg/cat) PO q8hr
Propylthiouracil (PTU)	Generic, Propyl-Thyracil	50- and 100-mg tablets	11 mg/kg PO q12hr
Prostaglandin F2 alpha (dinoprost)	Lutalyse	5-mg/ml solution for injection	Pyometra: Dog: 0.1-0.2 mg/kg SC once daily for 5 days Cat: 0.1-0.25 mg/kg SC once daily for 5 days Abortion: Dog: 0.025-0.05 mg (25-50 mcg)/kg IM q12hr Cat: 0.5-1 mg/kg IM for two injections
Pseudoephedrine	Sudafed and many others (some formulations have been discontinued)	30- and 60-mg tablets; 120-mg capsule; 6-mg/ml syrup	0.2-0.4 mg/kg (or 15-60 mg/dog) PO q8-12hr
Psyllium	Metamucil and others	Available as powder	1 tsp/5-10 kg (added to each meal)
Pyrantel pamoate	Nemex, Strongid	180-mg/ml paste and 50-mg/ml suspension	Dog: 5 mg/kg PO once and repeat in 7-10 days Cat: 20 mg/kg PO once
Pyridostigmine bromide	Mestinon, Regonol	12-mg/ml oral syrup; 60-mg tablet; 5-mg/ml injection	Antimychasthenic: 0.02-0.04 mg/kg IV q2hr or 0.5-3 mg/kg PO q8-12hr Antidote (nondepolarizing muscle relaxant): 0.15-0.3 mg/kg IM, IV
Pyrimethamine	Daraprim, ReBalance (Equine)	25-mg tablet Equine formulation (ReBalance) contains 250 mg sulfadiazine and 12.5 mg pyrimethamine per ml	Dog: 1 mg/kg PO q24hr for 14-21 days (5 days for <i>Neosporium caninum</i>) Cat: 0.5-1 mg/kg PO q24hr for 14-28 days

Appendix I—cont'd

Drug Name	Other Names	Formulations Available	Dosage
Quinidine gluconate	Quiniglute, Duraquin	324-mg tablets; 80-mg/ml injection	Dog: 6-20 mg/kg IM q6hr; 6-20 mg/kg PO q6-8hr (of base)
Quinidine sulfate	Cin-Quin, Quinora	100-, 200-, and 300-mg tablets; 200- and 300-mg capsules; 20-mg/ml injection	Dog: 6-20 mg/kg PO q6-8hr (of base); 5-10 mg/kg IV
Quinidine polygalacturonate	Cardioquin	275-mg tablet	Dog: 6-20 mg/kg PO q6hr (of base) (275 mg quinidine polygalacturonate = 167 mg quinidine base)
Racemethionine (DL-methionine)	Uroze, MethioForm, and generic. Human forms include Pedometh, Uracid, and generic	500-mg tablets and powders added to animal's food; 75-mg/5 ml pediatric oral solution; 200-mg capsule	Dog: 150-300 mg/kg/day PO Cat: 1-1.5 gm/cat PO (added to food each day)
Ranitidine	Zantac	75-, 150-, and 300-mg tablets; 150- and 300-mg capsules; 25-mg/ml injection	Dog: 2 mg/kg IV, PO q8hr Cat: 2.5 mg/kg IV q12hr, 3.5 mg/kg PO q12hr
Retinoids	See Isotretinoin (Accutane), Retinol (Aquasol-A), or Etretinate (Tegison)		
Retinol	See Vitamin A (Aquasol-A)		
Riboflavin (vitamin B ₂)	See Vitamin B ₂		
Rifampin	Rifadin	150- and 300-mg capsules	5-15 mg/kg PO q24hr
Ringer's solution	Generic	250-, 500-, and 1000-ml bags for infusion	55-65 ml/kg/day IV, SC, or IP; 50 ml/kg/hr IV for severe dehydration
Ronidazole	No formulation available; must be compounded	There are no commercial formulations. However, compounding pharmacies have prepared formulations for cats.	Dog: Dose not established Cat: 30-60 mg/kg/day PO for 2 wks
Salicylate	See Aspirin, acetylsalicylic acid		
Selegiline (deprenyl)	Anipryl (also known as deprenyl, and L-deprenyl); human dose form is Eldepryl	2-, 5-, 10-, 15-, and 30-mg tablets	Dog: Begin with 1 mg/kg PO q24hr; If there is no response within 2 months, increase dose to maximum of 2 mg/kg PO q24hr Cat: 0.25-0.5 mg/kg q12-24hr PO
Senna	Senokot	Granules in concentrate, or syrup	Dog: Syrup; 5-10 ml/dog q24hr; Granules: 1/2 to 1 tsp/dog q24hr PO with food Cat: Syrup: 5 ml/cat q24hr; granules: 1/2 teaspoon/cat q24hr (with food)
Septa (sulfamethoxazole + trimethoprim)	See Trimethoprim/sulfonamides		
Sildenafil	Viagra	25-, 50-, 100-mg tablets	Dog: 0.5-1 mg/kg q12hr PO; higher dose of 2-3 mg/kg q8hr may be needed in some cases
Silymarin	Silybin, Marin, "milk thistle"	Silymarin tablets are widely available OTC. Commercial veterinary formulations (Marin) also contain zinc and vitamin E in a phosphatidylcholine complex in tablets for dogs and cats.	30 mg/kg/day PO
Sodium bicarbonate (NaHCO ₃)	Generic, Baking Soda, Soda Mint	325-, 520-, and 650-mg tablets; injection of various strengths (4.2% to 8.4%), and 1 mEq/ml	Acidosis: 0.5-1 mEq/kg IV Renal failure: 10 mg/kg PO q8-12hr Alkalization of urine: 50 mg/kg PO q8-12hr (1 tsp is approximately 2 gm)

Drug Name	Other Names	Formulations Available	Dosage
Sodium bromide	No commercial form	Must be compounded	Same as potassium bromide, except dose is 15% lower (30 mg/kg potassium bromide is equivalent to 25 mg/kg sodium bromide)
Sodium chloride 0.9%	Generic	500- and 1,000-ml infusion	15-30 ml/kg/hr IV
Sodium chloride 7.5%	Generic	Infusion	2-8 ml/kg IV
Sodium thiomalate	See Gold sodium thiomalate		
Somatrem, Somatropin	See Growth hormone		
Sotalol	Betapace	80-, 160-, 240-mg tablets	Dog: 1-2 mg/kg PO q12hr (one can start with 40 mg/dog q12hr, then increase to 80 mg if no response) Cat: 1-2 mg/kg PO q12hr
Spironolactone	Aldactone	25-, 50-, and 100-mg tablets	2-4 mg/kg/day (or 1-2 mg/kg PO q12hr)
Stanozolol	Winstrol-V	50-mg/ml injection; 2-mg tablet	Dog: 2 mg/dog (or range of 1-4 mg/dog) PO q12hr; 25-50 mg/dog/wk IM Cat: 1 mg/cat PO q12hr; 25 mg/cat/wk IM
Succimer	Chemet	100-mg capsule	Dog: 10 mg/kg PO q8hr for 5 days, then 10 mg/kg PO q12hr for 2 more wks Cat: 10 mg/kg q8hr for 2 wks
Sucralfate	Carafate (Sulcrate in Canada)	1-gm tablet; 200-mg/ml oral suspension	Dog: 0.5-1 gm/dog PO q8-12hr Cat: 0.25 gm/cat PO q8-12hr
Sufentanil citrate	Sufenta	50-mcg/ml injection	2 mcg/kg IV, up to a maximum dose of 5 mcg/kg
Sulfadiazine	Generic, combined with trimethoprim in Tribrissen	500-mg tablet; trimethoprim-sulfadiazine 30-, 120-, 240-, 480-, and 960-mg tablets	100 mg/kg IV, PO (loading dose), followed by 50 mg/kg IV, PO q12hr (see also Trimethoprim)
Sulfadimethoxine	Albon, Bactrovet, and generic	125-, 250-, and 500-mg tablets; 400-mg/ml injection; 50-mg/ml suspension	55 mg/kg PO (loading dose), followed by 27.5 mg/kg PO q12hr (see also Primor)
Sulfamethoxazole	Gantanol	50-mg tablet	100 mg/kg PO (loading dose), followed by 50 mg/kg PO q12hr (see also Bactrim, Septra)
Sulfasalazine (sulfapyridine + mesalamine)	Azulfidine (Salazopyrin in Canada)	500-mg tablet	Dog: 10-30 mg/kg PO q8-12hr (see also Mesalamine, Olsalazine) Cat: 20 mg/kg q12hr PO
Sulfisoxazole	Gantrisin	500-mg tablet; 500-mg/5 ml syrup	50 mg/kg PO q8hr (urinary tract infections)
Tamoxifen	Nolvadex	10- and 20-mg tablets (tamoxifen citrate)	Veterinary dose not established; 10 mg PO q12hr is human dose
Taurine	Generic	Available in powder	Dog: 500 mg PO q12hr Cat: 250 mg/cat PO q12hr
Telezol	See Tiletamine-Zolazepam		
Tepoxalin	Zubrin	50-, 100-, 200-mg tablets	Dog: 10-20 mg/kg PO initially, followed by 10 mg/kg q24hr PO thereafter Cat: Safe dose not established
Terbinafine	Lamisil	125-, 250-mg tablets	Dog: <i>Malassezia</i> dermatitis: 30 mg/kg/day PO Cat: Dermatophytosis: 30-40 mg/kg PO q24hr
Terbutaline	Brethine, Bricanyl	2.5- and 5-mg tablets; 1-mg/ml injection (equivalent to 0.82 mg/ml)	Dog: 1.25-5 mg/dog PO q8hr Cat: 0.1-0.2 mg/kg PO q12hr (or 0.625 mg/cat, ¼ of 2.5-mg tablet) For acute treatment in cats: 5-10 mcg/kg q4hr SC or IM

Continued

Appendix I—cont'd

Drug Name	Other Names	Formulations Available	Dosage
Testosterone cypionate ester	Andro-Cyp, Andronate, Depo-Testosterone and other forms	100- and 200-mg/ml injection	1-2 mg/kg IM q2-4wk (see also Methyltestosterone)
Testosterone propionate ester	Testex (Malogen in Canada)	100-mg/ml injection	0.5-1 mg/kg 2-3 times/wk IM
Tetracycline	Panmycin	250- and 500-mg capsules; 100-mg/ml suspension	15-20 mg/kg PO q8hr; or 4.4-11 mg/kg IV, IM q8hr
Thenium closylate	Canopar	500-mg tablet	Dog: >4.5 kg: 500 mg PO once, repeat in 2-3 wks 2.5-4.5 kg: 250 mg q12hr for 1 day, repeat in 2-3 wks
Theophylline	Many brands and generic	100-, 125-, 200-, 250-, and 300-mg tablets; 27-mg/5 ml oral solution or elixir; injection in 5% dextrose	Dog: 9 mg/kg PO q6-8hr Cat: 4 mg/kg PO q8-12hr
Theopylline extended-release	Inwood Labs extended release	100-, 200-, 300-, and 400-mg tablets or 125-, 200-, 300-mg capsules	Dog: 10 mg/kg q12hr PO of extended-release tablet or capsule Cat: 20 mg/kg q24-48hr PO extended-release tablet or 25 mg/kg q24-48hr PO extended-release capsule
Thiamine (vitamin B ₁)	Bewon and others	250-mcg/5 ml elixir; tablets of various size from 5 mg to 500 mg; 100- and 500-mg/ml injection	Dog: 10-100 mg/dog/day PO or 12.5-50 mg/dog IM or SC/day Cat: 5-30 mg/cat/day PO (up to a maximum dose of 50 mg/cat/day) or 12.5-25 mg/cat IM or SC/day
Thiamylal sodium	No longer available; substitute Thiopental		
Thioguanine (6-TG)	Generic	40-mg tablet	40 mg/m ² PO q24hr Cat: 25 mg/m ² PO q24hr for 1-5 days, then repeat every 30 days
Thiomalate sodium	See Gold sodium thiomalate		
Thiopental sodium	Pentothal	Various size vials from 250 mg to 10 gm (mix to desired concentration)	Dog: 10-25 mg/kg IV (to effect) Cat: 5-10 mg/kg IV (to effect)
Thiotepa	Generic	15-mg injection (usually in solution of 10 mg/ml)	0.2-0.5 mg/m ² weekly, or daily for 5-10 days IM, intracavitary, or intratumor
Thyroid hormone	See Levothyroxine sodium (T ₄), or Liothyronine		
Thyrotropin, thyroid-stimulating hormone (TSH)	Thyropar, thyrogen	10-U vial; old forms difficult to obtain; thyrogen is 1000 mcg/vial	Dog: Collect baseline sample, followed by 0.1 U/kg IV (maximum dose is 5 U); collect post-TSH sample at 6 hr Cat: Collect baseline sample, followed by 2.5 U/cat IM and collect a post-TSH sample at 8-12 hr
Ticarcillin	Ticar, Ticillin	Vials containing 1, 3, 6, 20, and 30 gm	33-50 mg/kg IV, IM q4-6hr
Ticarcillin + clavulanate	Timentin	3-gm/vial for injection	Dose according to rate for ticarcillin
Tiletamine + zolazepam	Telazol, Zoletil	50 mg of each component per milliliter	Dog: 6.6-10 mg/kg IM (short term) or 10-13 mg/kg IM (longer procedure) Cat: 10-12 mg/kg IM (minor procedure) or 14-16 mg/kg IM (for surgery)
Tobramycin	Nebcin	40-mg/ml injection	Dog: 9-14 mg/kg IM, IV, SC q24hr Cat: 5-8 mg/kg IM, SC, IV q24hr
Tocainide	Tonocard	400- and 600-mg tablets	Dog: 15-20 mg/kg PO q8hr Cat: No dose established
Toluene	Vermiplex		267 mg/kg PO (of toluene), repeat in 2-4 wk

Drug Name	Other Names	Formulations Available	Dosage
Tramadol hydrochloride	Ultram and generic	Tramadol immediate-release tablets are available in 50-mg tablets	Dog: 5 mg/kg PO q6-8hr Cat: Safe dose not established
Trandolapril	Mavik	1-, 2-, and 4-mg tablets	Not established for dogs; human dose is 1 mg/person/day to start, then increase to 2-4 mg/day
Triamcinolone	Vetalog, Trimtabs, Aristocort, generic	Veterinary (Vetalog) 0.5- and 1.5-mg tablets. Human form: 1-, 2-, 4-, 8-, and 16-mg tablets; 10-mg/ml injection	Antiinflammatory: 0.5-1 mg/kg PO q12-24hr, then taper dose to 0.5-1 PO mg/kg q48hr (however, manufacturer recommends doses of 0.11 to 0.22 mg/kg/day)
Triamcinolone acetone	Vetalog	2- or 6-mg/ml suspension injection	0.1-0.2 mg/kg IM, SC, repeat in 7-10 days Intralesional: 1.2-1.8 mg, or 1 mg for every cm diameter of tumor q2wk
Triamterene	Dyrenium	50- and 100-mg capsules	1-2 mg/kg PO q12hr
Tribissen	See Trimethoprim-sulfadimethoxine combination		
Trientine hydrochloride	Syprine	250-mg capsule	10-15 mg/kg PO q12hr
Trifluoperazine	Stelazine	10-mg/ml oral solution; 1-, 2-, 5-, and 10-mg tablets; 2-mg/ml injection	0.03 mg/kg IM q12hr
Triflupromazine	Vesprin	10- and 20-mg/ml injection	0.1-0.3 mg/kg IM, PO q8-12hr
Tri-iodothyronine	See Liothyronine		
Trilostane	Vetoryl	10-, 30-, 60-, and 120-mg capsules; no formulations approved in US; must be imported	Dog: 3.9-9.2 mg/kg/day PO (most common dose is 6.1 mg/kg/day); adjust dose based on cortisol measurements
Trimeprazine tartrate	Temaril (Panectyl in Canada)	2.5-mg/5 ml syrup; 2.5-mg tablet	0.5 mg/kg PO q12hr
Trimethobenzamide	Tigan and others	100-mg/ml injection; 100- and 250-mg capsules	Dog: 3 mg/kg IM, PO q8hr Cat: Not recommended
Trimethoprim + sulfonamides (sulfadiazine or sulfamethoxazole)	Tribissen and others	30-, 120-, 240-, 480-, and 960-mg tablets with trimethoprim to sulfa ratio 1:5	15 mg/kg PO q12hr, or 30 mg/kg PO q12-24hr For <i>Toxoplasma</i> : 30 mg/kg PO q12hr
Tripelennamine	Pelamine, PBZ	25- and 50-mg tablets; 20-mg/ml injection	1 mg/kg PO q12hr
TSH (thyroid-stimulating hormone)	See Thyrotropin		
Tylosin	Tylocine, Tylan, Tylosin tartrate	Available as soluble powder 2.2 gm tylosin per tsp (tablets for dogs in Canada)	Dog, cat: 7-15 mg/kg PO q12-24hr Dog: For colitis: 10-20 mg/kg q8hr with food initially, then increase interval to q12-24hr
Urofollitropin (FSH)	Metrodin	75 U/vial for injection	75 U/day IM for 7 days
Ursodiol (ursodeoxycholate)	Actigall	300-mg capsule, 250-mg tablets	10-15 mg/kg PO q24hr
Valproic acid, divalproex	Depakene (valproic acid); Depakote (divalproex)	125-, 250-, and 500-mg tablets (Depakote); 250-mg capsule; 50-mg/ml syrup (Depakene)	Dog: 60-200 mg/kg PO q8hr; or 25-105 mg/kg/day PO when administered with phenobarbital
Vancomycin	Vancocin, Vancoled	Vials for injection (0.5 to 10 gm)	Dog: 15 mg/kg q6-8hr IV infusion Cat: 12-15 mg/kg q8hr IV infusion
Vasopressin (ADH)	Pitressin	20 U/ml (aqueous)	10 U IV, IM
Verapamil	Calan, Isoptin	40-, 80-, and 120-mg tablet; 2.5-mg/ml injection	Dog: 0.05 mg/kg IV q10-30 min (maximum cumulative dose is 0.15 mg/kg)
Vinblastine	Velban	1-mg/ml injection	2 mg/m ² IV (slow infusion) once/wk

Continued

Appendix I—cont'd

Drug Name	Other Names	Formulations Available	Dosage
Vincristine	Oncovin, Vincasar, generic	1-mg/ml injection	Antitumor: 0.5-0.7 mg/m ² IV (or 0.025-0.05 mg/kg) once/wk For thrombocytopenia: 0.02 mg/kg IV once/wk
Viokase	See Pancrelipase		
Vitamin A (retinoids)	Aquasol A	Oral solution: 5000 U (1,500 RE) per 0.1 ml 10,000-, 25,000-, and 50,000-U tablets	625-800 U/kg PO q24hr
Vitamin B ₁	See Thiamine		
Vitamin B ₂ (riboflavin)	Riboflavin	Various-size tablets in increments from 10 to 250 mg	Dog: 10-20 mg/day PO Cat: 5-10 mg/day PO
Vitamin B ₁₂ (cyanocobalamin)	Cyanocobalamin	Various-size tablets in increments from 25 to 100 mcg and injections	Dog: 100-200 mcg/day PO Cat: 50-100 mcg/day PO
Vitamin C (ascorbic acid)	See Ascorbic acid	Tablets of various sizes and injection	100-500 mg/day
Vitamin D	See Dihydrotachysterol or Ergocalciferol		
Vitamin E (alpha-tocopherol)	Aquasol E, and generic	Wide variety of capsules, tablets, oral solution available (e.g., 1000 units per capsule)	100-400 U PO q12hr (or 400-600 U PO q12hr for immune-mediated skin disease)
Vitamin K ₁ (phytonadione, phytomenadione)	AquaMEPHYTON (injection), Mephyton (tablets); Veta-K1 (capsules)	2- or 10-mg/ml injection; 5-mg tablet (Mephyton) 25-mg capsule (Veta-K1)	Short-acting rodenticides: 1 mg/kg/day IM, SC, PO for 10-14 days Long-acting rodenticides: 2.5-5 mg/kg/day and up to 6 wks IM, SC, PO for 3-4 wk Birds: 2.5-5 mg/kg q24hr
Warfarin	Coumadin, generic	1-, 2-, 2.5-, 4-, 5-, 7.5-, and 10-mg tablets	Dog: 0.1-0.2 mg/kg PO q24hr Cat: Thromboembolism: Start with 0.5 mg/cat/day and adjust dose based on clotting time assessment
Xylazine	Rompun and generic	20- and 100-mg/ml injection	Dog: 1.1 mg/kg IV, 2.2 mg/kg IM Cat: 1.1 mg/kg IM (emetic dose is 0.4-0.5 mg/kg IV)
Yohimbine	Yobine	2-mg/ml injection	0.11 mg/kg IV or 0.25-0.5 mg/kg SC, IM
Zidovudine (AZT)	Retrovir	10-mg/ml syrup; 10-mg/ml Injection	Cat: 15 mg/kg PO q12hr to 20 mg/kg q8hr (doses as high as 30 mg/kg/day also have been used)
Zolazepam	See Tiletamine-zolazepam combination		
Zonisamide	Zonegram	100-mg capsule	Dog: 3 mg/kg q8hr PO; it has also been administered to dogs at 10 mg/kg q12hr PO Cat: Dose not established

NOTE: Doses listed are for dogs and cats, unless otherwise listed. Many of the doses listed are extra-label or are human drugs used in an off-label or extra-label manner. Doses listed are based on best available evidence at the time of table preparation; however, the author cannot ensure efficacy of drugs used according to recommendations in this table. Adverse effects may be possible from drugs listed in this table of which author was not aware at the time of table preparation. Veterinarians using these tables are encouraged to check current literature, product label, and the manufacturer's disclosure for information regarding efficacy and any known adverse effects or contraindications not identified at the time of preparation of these tables.

IM, Intramuscular; IV, intravenous; OTC, over-the-counter (without prescription); PO, per os (oral); Rx, prescription only; SC, subcutaneous; U, units.

APPENDIX II

Treatment of Parasites

CLIFF MONAHAN, *Columbus, Ohio*

Helminths

Drug(s)	Species	Target Parasites	Route*	Veterinary Formulations
Emodepside/Praziquantel	Feline only	Roundworms, hookworms, <i>Dipylidium caninum</i> , <i>Echinococcus multilocularis</i> , <i>Taenia taeniaeformis</i>	Topical	Profender
Epsiprantel	Canine and feline	<i>Dipylidium caninum</i> , <i>Taenia</i> spp.	Oral	Cestex
Febantel/Praziquantel/Pyrantel Pamoate	Canine only	Roundworms, hookworms, <i>Trichuris vulpis</i> , <i>Dipylidium caninum</i> , <i>Echinococcus granulosus</i> , <i>Taenia pisiformis</i>	Oral	Drontal Plus
Fenbendazole	Canine	Roundworms, hookworms, <i>Trichuris vulpis</i> , <i>Giardia intestinalis</i> , <i>Taenia pisiformis</i>	Oral	Panacur
Imidacloprid/Moxidectin	Canine and feline	Roundworms, hookworms, <i>Trichuris vulpis</i> in dogs; <i>Dirofilaria immitis</i> prevention	Topical	Advantage Multi
Ivermectin	Canine and feline	Roundworms, hookworms, in cats, <i>Dirofilaria immitis</i> prevention in dogs and cats	Oral	Heartgard
Ivermectin/Praziquantel/Pyrantel Pamoate	Canine only	Roundworms, hookworms, <i>Dipylidium caninum</i> , <i>Echinococcus granulosus</i> , <i>Taenia pisiformis</i> , <i>Dirofilaria immitis</i> prevention	Oral	Iverhart Max
Ivermectin/Pyrantel Pamoate	Canine only	Roundworms, hookworms, <i>Dirofilaria immitis</i> prevention	Oral	Heartgard Plus, Iverhart Plus, TriHeart Plus
Milbemycin Oxime	Canine and feline	Roundworms, <i>Ancylostoma</i> spp., <i>Trichuris vulpis</i> in dogs; <i>Dirofilaria immitis</i> prevention	Oral	Interceptor
Praziquantel	Canine and feline	<i>Dipylidium caninum</i> , <i>Echinococcus</i> spp., <i>Taenia</i> spp.	Oral injectable	Droncit
Praziquantel/Pyrantel Pamoate	Feline only	Roundworms, hookworms, <i>Dipylidium caninum</i> , <i>Echinococcus multilocularis</i> , <i>Taenia taeniaeformis</i>	Oral	Drontal
Pyrantel Pamoate	Canine and feline	Roundworms and hookworms in dogs and cats	Oral	Nemex
Selamectin	Canine and feline	Roundworms and hookworms in cats; <i>Dirofilaria immitis</i> prevention in dogs and cats	Topical	Revolution

Protozoa

Drug(s)	Species	Target Parasite(s)	Route(s) and Frequency of Administration	Veterinary Formulations
Fipronil	Canine and feline	Fleas, lice, mites, ticks	Topical, monthly	Frontline, Frontline Plus
Imidacloprid	Canine and feline	Fleas, lice	Topical, monthly	Advantage
Imidacloprid/Permethrin	Canine only	Fleas, lice, mites, ticks	Topical, monthly	Advantix
Metaflumizone	Feline only	Fleas, lice	Topical, monthly	ProMeris for Cats
Metaflumizone/Amitraz	Canine only	Fleas, lice, mites, ticks	Topical, monthly	ProMeris for Dogs
Nitenpyram	Canine and feline	Fleas	Oral, daily	Capstar
Spinosad	Canine only	Fleas	Oral, monthly	Comfortis

Ectoparasites

Drug(s)	Species	Target Parasite(s)	Route of Administration and Dosages	Veterinary Formulations
Amprolium	Canine	<i>Isospora</i> spp.	Oral, 100 mg/kg SID, 7-10 days	Corid
Clindamycin	Canine and feline	<i>Toxoplasma gondii</i> (systemic infections)	Oral, 10-15 mg/kg BID, 14-28 days as needed	Antirobe
Doxycycline	Canine and feline	<i>Toxoplasma gondii</i> (systemic infections)	Oral 5-10 mg/kg BID, 28 days	Vibramycin
Fenbendazole	Canine and feline	<i>Giardia intestinalis</i>	Oral, 50 mg/kg SID, 3 days	Panacur
Imidocarb dipropionate	Canine and feline	<i>Babesia</i> spp., <i>Cytauxzoon felis</i>	IM or SC, 6.6 mg/kg; repeat in 14 days	Imizol
Metronidazole	Canine and feline	<i>Giardia intestinalis</i>	Oral, 25 mg/kg SID, 5 days	Flagyl
Nitazoxanide	Canine and feline	<i>Giardia intestinalis</i> , <i>Cryptosporidium</i> spp.	Oral, 100 mg/kg BID, 3 days	Alinia (Human) Navigator (Horses)
Ponazuril	Canine and feline	<i>Isospora</i> spp., <i>Toxoplasma gondii</i>	Oral, 15 mg/kg SID, 3 days; 30 mg/kg SID, 1 day	Marquis (Horses)
Sulfadiazine and Trimethoprim	Canine and feline	<i>Isospora</i> spp., <i>Toxoplasma gondii</i> (intestinal infections)	Oral, 30 mg/kg BID, 14 days as needed	Tribissen
Sulfadimethoxine	Canine and feline	<i>Isospora</i> spp., <i>Toxoplasma gondii</i> (intestinal infections)	Oral, 50 mg/kg day 1, then 25 mg/kg SID for 14-21 days as needed	Albon

*Follow manufacturer's recommendations for indicated use; see Appendix I, Table of Commonly Used Drugs, for extralabel use.

APPENDIX III

AAFCO Dog and Cat Food Nutrient Profiles

DAVID A. DZANIS, *Santa Clarita, California*

The Association of American Feed Control Officials (AAFCO) is a non-governmental body, but it is composed solely of representatives from agencies within individual states and territories, federal agencies such as the U.S. Food and Drug Administration (FDA), and foreign governments such as Canada. A primary function of AAFCO is the publication of a model feed bill, animal feed regulations, and ingredient definitions, all of which a state may adopt as a part of its own feed laws and regulations. A pet food that bears a "complete and balanced" label claim that does not, in fact, offer adequate nutrition is both misbranded and unsafe. To address this concern, included in the model pet food regulations are means of substantiating nutritional adequacy for complete and balanced dog and cat foods.

One method of substantiating nutritional adequacy requires that the product be formulated so that essential nutrient levels meet a prescribed profile. Historically, AAFCO relied on the publications of the National Research Council (NRC) as its authority with respect to the levels of nutrients that constituted a complete and balanced dog or cat food. However, to address several technical concerns regarding the applicability of the NRC recommendations to the practical formulation of pet foods, they were replaced by the AAFCO Dog and Cat Food Nutrient Profiles (Tables 1 and 2) in the early 1990s.

The profiles are the product of the AAFCO Canine Nutrition Expert (CNE) and Feline Nutritional Expert (FNE) Subcommittees, which met in 1990 and 1991, respectively. Nationally recognized experts from both academia and industry were convened to establish practical profiles based on commonly used ingredients. In addition to this author (at that time representing the FDA), members of the CNE included Dr. Jim Corbin, University of Illinois; Dr. Gail Czarnecki-Maulden, Westreco, Inc.; Dr. Diane Hirakawa, The Iams Company; Dr. Francis Kallfelz, Cornell University; Dr. Mark Morris, Mark Morris Associates; and Dr. Ben Sheffy, Cornell University. Added to the original members of the CNE were two new members on the FNE to bring additional expertise in the field of cat nutrition; Dr. Quinton Rogers, University of California-Davis; and Dr. Angele Thompson, Kal Kan Foods. Mr. Wenell Kerr of Westreco, Inc., also participated to provide statistical support to both subcommittees. The CNE and FNE met once again in 1995 to review and update both the dog and the cat food profiles. At the time of this writing,

a new AAFCO expert panel has been convened to review recent data and recommend revision of the profiles where appropriate.

Nutrient levels in the AAFCO Dog and Cat Food Nutrient Profiles are based on the CNE and the FNE members' knowledge of published and unpublished research, as well as their personal expertise and experiences in practical formulation. Much of the scientific data on nutrient requirements are based on studies using purified diets and the presumption of 100% bioavailability. However, since commercial products are composed of nonpurified, complex ingredients, allowances to account for the effects of ingredients, ingredient interactions, and processing on bioavailability were also considered in establishing nutrient levels. Comments on the bioavailability or the effect of processing and ingredient interaction on some nutrients are also added in the footnotes to tables.

In addition to minimum nutrient levels, the AAFCO Dog and Cat Food Nutrient Profiles also set maximum levels of intake of some nutrients. This was done out of concern that the risk of nutrient excess, rather than deficiency, was a concern with some pet foods. Thus maximum limits on the amounts of calcium, phosphorus, magnesium, fat-soluble vitamins, and most trace minerals in dog foods are established. Whereas the list of maximum levels for cat foods is not as extensive as that for dog foods, it should not be inferred that cats are more tolerant of nutrient excesses than dogs. Rather it reflects the paucity of information on the toxic effects of nutrients in cats. Establishing maximum levels arbitrarily might prove worse than no maximum at all. Setting a maximum level implies safety below that level, which the subcommittees could not reasonably ensure.

Replacing the previous "meets or exceeds the NRC recommendations" verbiage, the required label wording for reference to the nutrient profiles is that the product is "... formulated to meet the nutrient levels established by the AAFCO Dog (or Cat) Food Nutrient Profiles for ..." a given life stage. For both dog and cat foods, there are two separate AAFCO profiles: one for growth and reproduction (gestation and lactation), and one for adult maintenance. This allows foods formulated for adult dogs or cats to contain lower amounts of some nutrients, eliminating unnecessary excesses. Products that meet only the adult maintenance profile should include "maintenance" as its given life stage. Since products suitable for the more stringent nutrient requirements of growth and reproduction

Table 1

AAFCO Dog Food Nutrient Profiles*

Nutrient	Units DM Basis	Growth and Reproduction Minimum	Adult Maintenance Minimum	Maximum
Crude protein	%	22.0	18.0

Thiamine	mg/kg	1.0	1.0	
Riboflavin	mg/kg	2.2	2.2	
Pantothenic acid	mg/kg	10	10	
Niacin	mg/kg	11.4	11.4	
Pyridoxine	mg/kg	1.0	1.0	
Folic acid	mg/kg	0.18	0.18	
Vitamin B ₁₂	mg/kg	0.022	0.022	
Choline	mg/kg	1,200	1,200	

*Presumes an energy density of 3.5 kcal ME/g DM, based on the “modified Atwater” values of 3.5, 8.5, and 3.5 kcal/g for protein, fat, and carbohydrate (nitrogen-free extract, NFE), respectively. Rations greater than 4.0 kcal/g should be corrected for energy density; rations less than 3.5 kcal/g should not be corrected for energy. Rations of low-energy density should not be considered adequate for growth or reproductive needs based on comparison to the profiles alone.

†Although a true requirement for fat per se has not been established, the minimum level was based on recognition of fat as a source of essential fatty acids, as a carrier of fat-soluble vitamins, and on the amount needed to enhance palatability and to supply an adequate caloric density.

‡Because of very poor bioavailability, iron from carbonate or oxide sources that are added to the diet should not be considered in determining the minimum nutrient level.

§Because of very poor bioavailability, copper from oxide sources that are added to the diet should not be considered in determining the minimum nutrient level.

||Because processing may destroy up to 90% of the thiamine in the diet, allowances in formulation should be made to ensure that the minimum nutrient level is met after processing.

are also presumed to be adequate for adult maintenance, products meeting the growth and reproduction profile can list their intended use for either maintenance, growth, gestation and lactation, or “all life stages.”

Nutrient levels in the tables are expressed on a dry matter (DM) basis. To accurately compare levels for a

pet food as given in the guaranteed analysis portion of a label or elsewhere on an “as fed” basis, the values must first be corrected for moisture content. For most dry pet foods (10% moisture), “as fed” values should be multiplied by 1.1. For 75% moisture canned product, values should be multiplied by 4.0. The profiles are also set at

Table 2

AAFCO Cat Food Nutrient Profiles*

Nutrient	Units DM Basis	Growth and Reproduction Minimum	Adult Maintenance Minimum	Maximum
Crude protein	%	30.0	26.0	
Arginine	%	1.25	1.04

Taurine (extruded)	%	0.10	0.10	
Taurine (canned)	%	0.20	0.20	

*Presumes an energy density of 4.0 kcal ME/g DM, based on the "modified Atwater" values of 3.5, 8.5, and 3.5 kcal/g for protein, fat, and carbohydrate (nitrogen-free extract, NFE), respectively. Rations greater than 4.5 kcal/g should be corrected for energy density; rations less than 4.0 kcal/g should not be corrected for energy. Rations of low-energy density should not be considered adequate for growth or reproductive needs based on comparison to the profiles alone.

†Although a true requirement for fat per se has not been established, the minimum level was based on recognition of fat as a source of essential fatty acids, as a carrier of fat-soluble vitamins, to enhance palatability, and to supply an adequate caloric density.

‡If the mean urine pH of cats fed ad libitum is not below 6.4, the risk of struvite urolithiasis increases as the magnesium content of the diet increases.

§Because of very poor bioavailability, iron from carbonate or oxide sources that are added to the diet should not be considered in determining the minimum nutrient level.

||Because of very poor bioavailability, copper from oxide sources that are added to the diet should not be considered in determining the minimum nutrient level.

¶Add 10 IU of vitamin E above minimum level per gram of fish oil per kilogram of diet.

#Vitamin K does not need to be added unless diet contains more than 25% fish on a dry matter basis.

**Because processing may destroy up to 90% of the thiamine in the diet, allowances in formulation should be made to ensure that the minimum nutrient level is met after processing.

††Biotin does not need to be added unless diet contains antimicrobial or antivitamin compounds.

‡‡Methionine may be used to substitute for choline as a methyl donor at rate of 3.75 parts for 1 part choline by weight when methionine exceeds 0.62%.

presumed energy densities (3.5 kcal ME/g DM for dog foods, 4.0 kcal ME/g DM for cat foods). Since a dog or cat is presumed to eat less of a high-calorie food, the levels of the nutrients must be proportionally higher in order for the animal to meet its needs with lower food intake. Thus products very high in caloric density should also be corrected for energy content before comparisons with the profiles are made.

The AAFCO Dog and Cat Food Nutrient Profiles and accompanying information on using the tables are published annually in the AAFCO Official Publication. Information on AAFCO and how to obtain a copy of the AAFCO Official Publication can be found on its website (<http://www.aafco.org>) or by writing to: Ms Sharon Krebs, AAFCO Assistant Secretary-Treasurer, P.O. Box 478, Oxford, IN 47971.

surgery for, XIII:746-747
- Vesiculobullous lesions, from drug hypersensitivity, XIII:557t
- Vestibular control, normal, 1097-1098
- Vestibular disease, 1097-1101, 1098t, 1099f, 1100f
central, 1098t, 1100-1101
diagnosis and management of, XIII:966-971
differentiation of peripheral vs. central, 1098t
hypothyroidism and, XIII:327, XIII:974
peripheral, 1098-1100, 1098t
- Vestibular system, anatomy of, XIII:966-967
- Vestibulovaginal stenosis, 1016
- Veterinary literature, sources of, XIII:3t
- Vetsulin, use of, in dogs, 196-197
- Vidarabine, for feline herpesvirus, 1188
- Video-assisted thoracoscopy (VAT), 673-674
- Vinblastine
administration protocol for, XIII:464
as chemotherapy, 311, XIII:467
for mast cell tumors, 376, 377b
- Vinca major and V. minor, 151t
- Vincristine
administration protocol for, XIII:463-464
as chemotherapy, 311, XIII:467
for canine lymphoma, 336, 337t
for feline gastrointestinal lymphoma, 342, 342t
for hemangiosarcoma, 330
for thrombocytopenia, 286, XIII:440
- Vinorelbine (Navelbine), as chemotherapy, 312t, 313
- Viral diseases
causing anterior uveitis, 1203b, 1204
control of, in catteries, 1299-1305
- Viral encephalitis, 1071-1072
- Viral myocarditis, 804-808, 805t
- Viral skin disease, in cats, 441-443
- Virchow's triad, 24, 696
- Virus isolation
for canine influenza, 1293-1294
for feline herpesvirus, XIII:1058
- Virus(es)
causing pregnancy loss, 987
effectiveness of disinfectants and antiseptics against, XIII:259t
incriminated in disseminated intravascular coagulation, XIII:191t
- Vision
evaluation of, 1163-1164, 1170
pathways for, 1169f, XIII:1046f, XIII:1048f, XIII:1048t
lesions in, 1172t
testing for, XIII:1038-1039
- Visual-evoked potentials, for evaluating blindness, 1164
- Vitamin A
for sebaceous adenitis, 452
toxicity, 111
- Vitamin B
for myopathies, 1115-1116
supplementation in liver disease, 569, 572
- Vitamin B₁, deficiency of, furosemide and, XIII:712
- Vitamin B₁₂
malabsorption of, XIII:418
measurement of, XIII:639
supplementation of, with exocrine pancreatic insufficiency, XIII:657
- Vitamin C, for acetaminophen toxicity, 113, 114t
- Vitamin D
and paraneoplastic hypercalcemia, 344t, 345
preparation of, for, XIII:343
supplementation of
for hypocalcemia, 245-247, 245t, XIII:341
for puerperal tetany, 1002
with hyperparathyroidism, 250
toxicity, 111
- Vitamin D3 analog medications, causing nephrotoxicity, 160b
- Vitamin E
for hepatic fibrosis, XIII:681
for hepatic support, 554-555, 569, 572-573
in dermatology, XIII:538
supplementation of, with exocrine pancreatic insufficiency, XIII:657
- Vitamin imbalances, in homemade diets, 167
- Vitamin K
deficiency of, with liver disease, 555, 556, 573, XIII:695
for exocrine pancreatic insufficiency, XIII:657
- Vitamin K₁
for rodenticide toxicosis, 113, 114t, 117-119, XIII:207t, XIII:208-209, XIII:211
supplementation of, in liver disease, 573, 579
toxicity of, 575
- Vitamin(s), in parenteral nutrition
deficiencies of, XIII:88
supplementation of, XIII:83t
- Vitreous
drug therapy for, 1148, 1148t
humor opacification, causing blindness, 1165
opacification, blindness from, XIII:1039
- Vitreous centesis, for evaluating blindness, 1164
- Vizsla(s), sebaceous adenitis in, XIII:572-573
- Vogt-Koyanagi-Harada-like syndrome, affecting eyelids, 1183
- Volume overload, fluid therapy and, 51-54
- Voluven (Fresenine Kabi), 64-65
- Vomiting
chronic, in dogs, 492-497
control of, in cats, 574-575
fluid therapy for, 50
from uremia, XIII:864
induction of, 112-113, 113t
metoclopramide for, XIII:614-615
- von Willebrand's disease
autosomal recessive inheritance of, XIII:910t
diagnosis and treatment of, 277-279, XIII:434-438
genetic test for, 1057t
platelet dysfunction and, XIII:442
- von Willebrand's factor
effect of hydroxyethyl starch on, 64
effect of hypothyroidism on, XIII:328
factors affecting, 278
- Voriconazole, for fungal rhinitis, 614
- Vulva, surgery of, 1012-1013, 1013f
- Vulval softening, 976
- Vulvar hypoplasia, 1013-1014, 1015f
- Vulvoplasty, 1010
- VVI pacing systems, 718t, 719-721
- W**
- Warfarin (Coumadin)
as anticoagulant therapy, 25
changing from heparin therapy to, 696
for aortic thromboembolism, 814, 824
for prevention of thrombi, 696
- Water
balance, XIII:831
intake, normal physiology of, 844
- Water deprivation testing, 849-850
evaluation of, XIII:834
for diabetes insipidus, XIII:325
procedure for, XIII:833-834
- Weakness, as neurologic manifestations of hypothyroidism, XIII:974
- Weight gain
during gestation and lactation, 1004f
effect of early neutering on, 1021-1022
- Weight loss
for chronic bronchitis, 645
for tracheal collapse, 633
from uremia, XIII:864
strategy, 192-195
- Weight shifting, 1132
- Weimaraner(s)
growth hormone deficiency of, XIII:519
recurrent infections in, XIII:449
- West Highland white terrier, inherited copper hepatitis, 561
- Western red cedar essential oil, 152t
- Wheat gluten contamination, 165-168
- Whelpwise veterinary orders, 995f
- Whippet(s), avermectin toxicosis in, 125-127
- Whipple's disease, 521
- Whipple's triad, XIII:358
- White willow toxicity, 152
- Windhound(s), avermectin toxicosis in, 125-127
- Windshield washer fluid toxicity, 134-135
- Wire shielding, 127
- Wobbler syndrome. *See* Cervical vertebral instability-malformation syndromes
- Wolbachia, 841
- Wolff-Parkinson-White syndrome, supraventricular tachycardia and, XIII:728-729
- Wood's lamp examination, XIII:529
for dermatophytosis, 457, XIII:578
- Woodworm essential oil, 152t
- World wide websites on infectious diseases, XIII:1114t
- Wormseed essential oil, 152t
- Wounds
degloving or shearing, XIII:1032-1035
hyperbaric oxygen for, 601-602
- X**
- X-linked inheritance, in dogs, XIII:909, XIII:910t
- X-linked severe combined immunodeficiency (XSCID), X-linked inheritance of, XIII:910t

Xanthine

compound uroliths with, XIII:876t
crystalluria, 851t, 854, 854f

Xanthomatosis, 462-463

Xenobiotics, 159

Xerophthalmia. *See* Keratoconjunctivitis sicca

XX sex reversal, 1035-1037, XIII:905

Xylazine

adverse reactions of, in dogs, XIII:240t

epidural use of, XIII:128

for canine retrograde ejaculation, 1050

for neurologic and musculoskeletal pain, 1128t

use of, XIII:122

in toxicities, 97f, 113t

Xylitol toxicity, 109, 139-140

Y

Yersinia enterocolitica, causing neonatal

diarrhea, XIII:626t, XIII:627t

Yesterday-today-and-tomorrow plant ingestion, 140-141

Yohimbine

adverse reactions of, in dogs, XIII:240t

for canine retrograde ejaculation, 1050

Yorkshire terrier(s), hepatoportal microvascular dysplasia of, XIII:682-686

Yucca schidigera extracts, for flatulence, 526

Z

Zafirlukast, for feline airway inflammation, 656

Zalcitabine, for feline retrovirus, 1281t

Zantac. *See* Ranitidine (Zantac)

Zanthane urolithiasis, breeds at risk for, 857t

Zidovudine

for feline immunodeficiency virus, XIII:287, XIII:290

for feline leukemia virus, XIII:283-284

for feline retrovirus, 1281t, 1282

Zileuton, for feline airway inflammation, 656

Zinc

deficiency of, liver disease and, XIII:695

for copper-associated hepatitis, 562

for hepatic fibrosis, XIII:680t, XIII:681

malabsorption of, in bull terriers, XIII:519

plasma concentrations of, 562

responsive dermatosis, 1180-1181

Zinc acetate, for flatulence, 526

Zinc gluconate shampoos, 412t, 413, 414, 414t

Zinc otic, 430t

Zinc phosphide toxicosis, 93, 118-119, XIII:212

Zinc sulfate floatation, 667-671

Zinc toxicosis, 114t, 115, 855, 855b, 856b, 857, 859

treatment of, XIII:209

Zinc-responsive, dermatosis of eyelids, XIII:1052

Zolazepam, adverse reactions to, XIII:240t, XIII:241t

Zoledronate, for hypercalcemia of malignancy, 346f, 347

Zollinger-Ellison syndrome, XIII:617

Zonisamide, for seizures, 1068-1069

Zoonosis. *See also* specific disease, e.g.,

Toxoplasmosis

of *Bartonella* spp. infections, 1241-1245, XIII:303, XIII:306-307

of *Brucella canis*, 986, 1234

of *Chlamydia felis*, 1186

of dermatophytosis, 457-461, 458b

of *Helicobacter*-associated gastric disease, 492-497

of leishmaniasis, 1252-1254

of leptospirosis, 1239-1240

of methicillin-resistant *Staphylococcus aureus*, 449-450

of mycobacteriosis, XIII:1116-1118

of pet birds, XIII:1113-1116, XIII:1114t-1115t

of rabies, XIII:294-295 (*See also* EVOLVE)

of salmonella, XIII:1123-1125

with reptiles, XIII:1187

of toxoplasmosis, 1257-1258, 1257b, XIII:313-314

Zymox otic, 430t
